### ADDRESS BY THE PRESIDENT, JOHN. B. ROBERTS, A. M., M. D.

#### SOME DEFECTS IN ANATOMICAL TEACHING IN THE MEDICAL SCHOOLS OF THE UNITED STATES.

It has been truly said that anatomy and physiology are the foundation upon which the whole structure of medical education is built, and that consequently these sciences must be taught with exhaustive thoroughness and made the permanent intellectual property of the student.

The best medical schools in this country, with their four years' graded course requisite for the medical degree, have now attained an excellence probably not inferior to any similar educational institutions in the world. There still exist here, however, numerous useless and low-grade medical schools, destined to be soon destroyed by the rapidly increasing number of State medical examining boards. In some of the former class of schools, and in nearly all of other grades, anatomical teaching

has not reached the standard which the essential character of the subject demands. A consideration of the causes of this defective instruction and a search for efficient remedies seem appropriate. It is my hope that you who are present will discuss the statements of this address freely and fully, so that each of us may thereby find suggestions of value in elevating and improving the work done in our own schools and States.

It is a notorious fact that few of our students have any knowledge of biology when they begin the study of human anatomy. I know of but three schools in the United States (Johns Hopkins University, University of Michigan, and Hahnemann Medical College of Philadelphia) where a preliminary examination in elementary biology is required. Although an entrance examination in physics is enforced by many medical schools, there are others which admit without any such requirement. In those which submit students to this preliminary test, the examination is probably confined to very elementary questions. Several of our best schools still allow young men to begin the medical curriculum without any previous study of Latin. It is a little embarrassing to know that students entering homeopathic colleges are required by the American Institute of Homeopathy to possess a broader general education than is demanded of our students by the American Medical Association, the Association of American Medical Colleges, or our best medical schools. The preliminary educational requirements of the Hahnemann Medical College of Philadelphia include botany, chemistry, biology, physics, and Latin. Certainly not more than one or two schools include all of these topics in the entrance examination. It is not difficult to appreciate the confused ideas of human anatomy obtained by a first-year pupil, who knows little physics, less biology, and no Latin. What wonder that he fails to remember the names of the bones and muscles; and is filled with consternation when asked to mention an instance in the human body of a lever of the third class. He has no conception of the meaning of the descriptive Latin names of anatomical structures; wonders what is meant by "lever" and other mechanical terms; and is at a loss to know the significance of the terms "dorsal," "ventral," and "thoracic," and iter a tertio ad quartum ventriculum. Did not I, as a student, sit next to a man who was unable to understand the function of certain laryngeal structures because the professor attributed to them a mysterious use called "phonation?" Yet, under our present system such students listen to lectures on osteology, syndesmology, and myology and are expected to learn practical anatomy by dissecting the human body. To call such indecent butchery dissection is a farcical misnomer, as every demonstrator of anatomy knows. It would be much better to let these ill-trained hands learn the difference between muscle and fascia, nerve and vessel—which is about all such bungling teaches them—upon the dead bodies of the lower animals, and postpone dissection of human cadavers until the second or third year of the course.

Ebers has told in fiction of the Egyptian physician who, in the fourteenth century before Christ, ran the risk of condemnation by his heathen gods in order to obtain a human heart for studious dissection. You may remember his chagrin at finding his dearly bought prize so like that of the brutes he had often slaughtered in his quest for knowledge. Let the student of to-day begin his anatomical studies on the body of a dead cat and he will learn much that will enable him to prosecute investigations in human anatomy with the ease of one to whom its fundamental principles are already known.

One of the most detrimental results of the acceptance of medical students without preliminary education is that they have had no educational training in using their eyes and hands. An hour's stay in any dissecting room will prove this point. Here is a man holding his forceps as if they were fire tongs, there one making a fruitless attempt to put an edge on his scalpel.

Few students can describe what they see, and still fewer can make the crudest diagram of their findings. In scientifically conducted anatomical laboratories pupils should be required to describe orally or in writing what they uncover and

should make drawings of the more important features. This method is adopted in nonmedical schools and in the study of histology and pathology in some medical institutions. It is undoubtedly the true method of educating the mind, which is not a receptacle to be simply filled with statements thrown into it from the lips of teachers. That which enters by the ears may lead to culture; but Nasmyth, the Scotch engineer, spoke truly when he wrote "the eyes and the fingers—the bare fingers—are the two principal inlets to sound practical instruction." Who doubts that the anatomical discoveries of Ruysch in the early part of eighteenth century were due to his possessing "the hands of a fairy and the eye of a lynx?" A recent writer on education avers that only in Germany and such countries as neglect to educate the young by means of manual training do we find men of learning who can scarcely sharpen a pencil without cutting their fingers. My experience in post-graduate teaching convinces me that for this reason good operative surgery is impossible for some very intelligent physicians.

Manual training is valuable moreover, because as Felix Adler has said, hand culture brings brain culture. We need not only the worth and beauty of the object made, but also the psychological result brought by the effort for the utilitarian end. Physicians know that Seguin actually created intelligence in idiotic brains by manual training, and that mental discipline must not be too much subordinated to mechanical accuracy. The medical growth of not a few capable minds has been dwarfed by modern instruments of clinical precision. The time has certainly come when the medical schools of the United States should insist upon a preliminary examination in elementary biology. As soon as this requirement can be extended to include a certain amount of laboratory work in biology, students will have sufficient deftness and manual dexterity, added to their preliminary knowledge of natural history, to fit them for intelligently studying descriptive and practical human anatomy. As you probably know, the British five years' medical course is reduced to four years in a medical school, if the registered student has previously graduated in arts or sciences at a recognized university requiring a year in physics, chemistry, and biology. If no such general education has been obtained these subjects are studied during the early part of the professional curriculum, which is then of necessity five years in length. In France the preliminary education of one who aspires to become "Docteur en Medicine" must show evidence of having had instruction in natural history as well as in all topics of general education. Germany and Italy also require a preliminary knowledge of natural history, as probably do all the European nations except Belgium. In Brazil, and I think in the other Latin-American countries, a biological requirement is a necessary part of the preliminary education of those who purpose beginning medical studies. A young man desirous of entering a medical school had much better wait a year, and devote that time to biology, chemistry, physics, and Latin than to attempt to begin professional study without an elementary acquaintance with these subjects. The University Extension courses will, in many sections of the country, give him the needed opportunity. If no such courses are accessible, a few books, even without a teacher, will answer the purpose.

If it be true that much unsuccessful anatomical teaching is due to the poor quality of the recipients, it is none the less demonstrable that a more extended influence for evil is exerted by the inferior mental qualifications of teachers and the unscientific methods of teaching permitted in some schools. This is, to a certain extent, the result of a custom that permits a professor, once appointed, to hold his position without forcible criticism until he dies or resigns, and prevents the faculty as a body influencing or regulating the manner or mode of instruction. The occupant of a professorial chair is practically an autocrat by courtesy.

Puschmann says that in the eighteenth century anatomical demonstrations on dissected bodies were frequent in many European universities, but that "in other places the neglect of anatomical demonstration was caused not so much by a

scarcity of bodies as by the idleness and ignorance of the professors." Such a statement, it is to be feared, is not altogether inapplicable to the anatomical instruction now given in some quarters of the United States. Some men of great learning can not teach. The faculty of imparting knowledge is distinct from the faculty of acquiring knowledge. To teach is not simply to tell, but is to make the fact stated so interesting and so clear that it assumes a living importance and is eagerly sought and intelligently retained by the hearer as a part of himself. A teacher must draw bold, clear outlines, omitting details, and repeating essentials until his pupils have a mental framework, upon which they themselves may erect more elaborate structures at a future time.

He who has not the power to select the essentials and lead the scholar to reason and observe is destitute of the teaching instinct. Then his lectures become mere recitations as wearisome to himself as to his involuntary hearers. The true teacher furnishes his pupil with compass and chart; no more. The latter must select his route and reach his harbor by the exercise of those intellectual powers which have been given him. It is experience and not memory that has been fitly called the mother of ideas.

Few teachers of to-day read their lectures on anatomy; but in some cases the lecture is still as lifeless as if read from manuscript or text-book, and destitute of either demonstration or true teaching. Didactic teaching can not be entirely relinquished, but it has little place in anatomy. Demonstration by specimen, dissected cadaver, blackboard diagram, and living model must be the chief reliance of the professor of anatomy who desires to hold the attention of his class and make anatomy what it is, one of the most interesting branches in the medical curriculum. Not many students will be absent from the lecture hour devoted to anatomy if they know that the statements read in their text-books are to be verified by electrical stimulation of the muscles on the nude model; that they are to see with their eyes and feel with their hands the difference between artery, vein, and nerve; that the teacher will create in colored crayon on the blackboard the diagram illustrating the relations of bone, muscle, and viscus; that the dissected cadaver will be studied in the standing posture; that the muscles of expression will be illustrated by photographs and etchings of public characters; that surface anatomy will become interesting because studied on reproductions of the famous works of ancient Greek art.

Muscular actions can only be taught effectively by voluntary use of the muscles of nude models, or by their involuntary contraction induced by the electrical current. Bones and other specimens in the hands of the instructors are of little value to the student seated 20 feet away. This distance effectually prohibits the latter from seeing the fissures, grooves, and foramina so learnedly mentioned by the teacher, who is perhaps simply reading for his own enlightenment the lettering printed on the bone. Even gigantic models in the hands of the teacher are less advantageous than duplicate specimens in the hands of the students during the time of instruction. Some teachers fail to appreciate that an elaborate picture, though valuable for reference by one who has known the anatomical region, is of little service to a student. The crudest diagram, made before the latter's eyes, conveys the idea and fixes it in his brain. A piece of chalk and a blackboard are imperatively demanded whenever and wherever anatomy is to be taught. Yet I recall the dissecting room of a well-known medical school which for years had no blackboard, no chalk, and no skeleton within its walls.

Occupants of chairs of anatomy not infrequently look upon their positions as temporary, and long for the occasion when they may be transferred to a department in which they feel more interest. Who does not know professors of anatomy that promptly became professors of surgery or obstetrics when the opportunity arose? One can as little expect such temporary anatomical chairs to be filled with enthusiastic and successful teachers, as to find proper teaching of applied medical and surgical anatomy at the hands of physicians whose daily work is literature or life

insurance. Again, it is not reasonable to expect those whose early education has been defective to be able to teach the mutual relations of anatomy to biology, mechanics, and psychology. The student needs a wide preliminary education in general knowledge; but the teacher of anatomy is helpless without it.

No criticism is too severe for the system that places first and second course medical students in one class room to hear the same didactic lectures on anatomy. Such a parody of instruction is probably unknown except in medical schools. To compel half of the class to hear what they can not possibly understand, to force the other half to listen to much that they have already learned, is recognized as idiocy by every one, except the professional phonograph that each year repeats at a given hour the words which successive classes have received as instruction. Teaching that is not graded so as to lead step by step to higher knowledge is unworthy the name. It is impossible to compute the lost hours, undeveloped intellects, and disasters in medical practice due to this almost distinctively American folly. This undesirable method of teaching has been retained in the department of anatomy longer than in some other departments, because the important new facts to be taught in anatomy have been less numerous and conspicuous; therefore the whole subject can be pretty completely discussed in one session of lectures.

No method of instruction fulfills its mission if it does not develop the habit of independent investigation and work. Pupils need to be taught the manner of instituting and following out original inquiries and the use of the literature of a subject. Few colleges attempt to thus arouse the powers of observation and to sharpen the senses; for the prizes offered in some schools for a record of anomalies found in the dissecting room scarcely deserve consideration in this connection. Opportunities for original research in human anatomy are now given, and such work is encouraged at the Harvard University Medical School, The College of Physicians and Surgeons of New York, and in the medical department of Clark University, at Worcester, Mass. The last institution, however, confers no degrees in medicine and does not partake of the character of a school for undergraduates. Didactic instruction at the hands of teachers who never contribute a single new fact or thought to anatomical or medical literature is not calculated to encourage a spirit of scientific inquiry in students. The demonstrated usefulness to the scientific world of a teacher's original labor is a powerful stimulant to investigation and scientific rivalry among his pupils. The need of such opportunity and example is much felt in our schools.

In certain things we need to return to methods employed in the middle ages, but later overlooked or forgotten. In the beginning of the fifteenth century naked men were used to demonstrate anatomical facts, and it is possible that outline diagrams of the deeper structure were made on the bare skin. Experience with students has abundantly shown me that such "anatomical clinics" meet with great favor. To group in one lecture several nude models representing the effects of disease on anatomical landmarks is most valuable and essential in teaching and sustaining interest in clinical anatomy. "Clinical conferences," in which before his fellows the advanced student points out and demonstrates anatomical relations upon the living subject, develop a habit of thorough investigation of medical and surgical cases. Its subsequent value in diagnosis is easily appreciated.

This form of anatomical teaching is manifestly impossible to an instructor who has no practical knowledge of disease conditions. The necessity for comparative anatomy, morphology, embryology, and anthropology in a perfectly arranged anatomical curriculum may require a portion of the instruction to be given by a biologist, pure and simple; as long, however, as a medical school is to train medical practitioners the demand for a physician or surgeon to teach medical, surgical, and artistic anatomy will be imperative. The school that provides an enthusiastic biologist for the one purpose and a practicing doctor for the other will best fill the hours devoted to anatomy in the college course.

The lengthening of the medical curriculum in all schools to compel attendance on four college courses would give time for laboratory work in embryology and com-

parative anatomy. Graduation should then be deferred until the age of 22 years, as is now done in one school (Woman's Medical College of Pennsylvania).

The museums found in medical colleges lose much of their teaching value because the students have limited access to the specimens. Bones and dissected preparations, both wet and dry, of normal anatomy should be put in the student's hands for comparison with his own dissections and the text-book illustrations. In most cases the teacher alone handles the museum specimens. Wet preparations demonstrating normal regional anatomy are almost unknown in our college collections.

The work done by students in the anatomical rooms would be of a much higher grade if each member of the class was required to draw, even in crude outlines, the structures uncovered by his dissections, and under the guidance of an instructor to demonstrate his findings to his fellows. The necessity of preserving cadavers in this country by vascular injection with zinc chloride and similar decolorizing agents militates to a certain degree against fine work in our dissecting rooms. The adoption of the principle of cold storage by some schools (Bellevue Hospital Medical College, Chicago Medical College, medical department of Western Reserve University) shows a way out of the dilemma.

Examinations in anatomy, which might be public, should be conducted at various periods of the course. Those in the early part ought to be restricted to osteology and similar elementary topics; but the later and more difficult examinations in regional, medical, surgical, and artistic anatomy should be so conducted as to require the use of the earlier knowledge, and include demonstrations of surface anatomy and of dissections. A substitution of English terms for the Latin nomenclature, still largely retained in anatomy, would aid the average medical pupil to understand anatomical mechanics and remember the facts which he has presented to him. Much was gained in European schools when the mediæval practice of teaching medicine in debased Latin was relinquished. The professor who had to use the vernacular was compelled to be accurate in statement and clear in expression, and could no longer hide his ignorance in high-sounding Latin sentences imperfectly understood by his class.

The true solution of the educational problem in medicine is the discontinuance of the isolation existing between medical schools and schools whose object is general education and culture. Every medical school should be an integral part of a college or university, and should not be managed by men separated from the wholesome educational atmosphere which surrounds institutions devoted to learning in its broadest sense. The perpetuation and organization of isolated medical schools has been the cause of manifold defects in medical teaching, and has ended in making medical pedagogics an undeveloped science. The educational and educative friendships, even the hostilities, engendered by a combination of medical and academical schools would bring about better preliminary qualifications in medical students and more advanced methods of teaching in professors. It is the school and the man in the corner who never comes in contact with his superiors, that fails to improve his methods of work. The valuable "courses preparatory to medicine" now found in several universities, would become more numerous; and more youths, looking forward to a medical career, would begin their studies in such courses, if the university and the medical college were everywhere combined. Thus the study of medicine would be a gradual development of the mind and not a mere attempt to crowd technical facts in the memory; a process in violation of the first principles of education, and one which makes many medical journeymen, but few medical masters.

Universities, academies, and all literary schools would be benefited by the association with medical colleges, as it would lead to even greater modification of the former rigid classical course by the development of the departments of natural science and languages. This change would meet with the approval of many thinkers, among others the Emperor of Germany, who, you remember, has in recent years shown the value of youthful energy by insisting upon the necessity of modifying the strict and unyielding classical curriculum so long enforced by the German universities.

## PAPERS READ BEFORE THE SECTION.

## THE DISSECTING ROOM.

By E. W. HOLMES, M. D., of Philadelphia, Pa.

I had anticipated the pleasure of reviewing the various problems in the practical management of the anatomical room, in order to derive advantage from the experienced discussion and criticism of those present, but the exigencies of time and space enjoin the omission of many.

I would not have ventured upon the selection of this topic in this presence were it not for the evident neglect of this important branch of medical study of late years. That anatomical study was the basis of all medical knowledge, that a dissecting room, a supply of bodies, and a corps of teachers were absolutely necessary, have always been axioms. But more than that, what has been done in the majority of the schools. Look at the immense improvements in other branches. Twenty-five years ago well-equipped physiological and chemical and physical laboratories were uncommon; pathological museums were almost unknown, except in name, and practical hygiene and bacteriology were not in existence. To-day the opportunities for research in any one of these would busy a lifetime, but in anatomy we stand only on the basis of the needs of a quarter of a century ago. Formerly, anatomy claimed a good one-seventh of the required studies; to-day, it but weakly elbows a space with twenty ologies and specialties which have been elevated by their more enthusiastic advocates.

We often estimate the speed of our train by the rapidity with which we rush by stationary objects; and conversely, as practical anatomists, we can see how we have stood still by the rapid passing of the collateral branches which have asserted their importance and taken to themselves the time and attention which our branch needs.

One of the main reasons has been the teaching methods in vogue--the more instruction by lecturing, the fewer instructors required—which has practically resulted in the added emphasis of the lecture system and the minimizing of the personal supervision in dissection. The method of bedside instruction in medicine and surgery does not obtain, as it should, in the dissecting room of to-day. This is peculiarly unfortunate. Lecturing methods are especially ill fitted for the impressing of our facts. Really, the exigencies of practice of medicine and surgery demand the application of these facts through the eye and hand and not by the ear, and yet the best lecturer can not exhibit his dissection to more than 50 students seated around him, and when you remember that in the larger schools often there are 700, you appreciate how really ineffective is the method. Not that I deprecate in the least the value of the experience of the accomplished anatomist who directs in his lecture the novice in his studies; but a lecture course can not teach, it can only point out the way, while the real learning must be done by the student himself in his room and at the cadaver.

The emphasis, however, is ever laid upon the attendance upon the hours of the lecture, and the compulsion is upon the examination upon those lectures. There is hardly a medical school that absolutely insists upon the student being present at fixed hours in the dissecting room. Dissecting, of course, is obligatory, and it sets apart certain periods for dissecting when the student can come if he wishes to, like the ancient almanacs that stretch across the whole month's page, "Look out for rain about this time." Students are divided into small sections for bedside instruction in clinical medicine and surgery, but "nary a bit" for dissecting work. Who ever heard of modernized teaching facilities for the dissecting room? There is nothing beyond the corpse, the cadaver, and the corps of teachers, and a skeleton

or two, and the few nude pictures of three decades back. The museum is for the illustration of the lectures, and is separated far and wide from the anatomical room. Then the anatomical room itself—it is a dirty place, you know. If there is any extra paint or adornment, it does not go there. It is the most unattractive room in the school, and the most inaccessible.

I need not apologize for wishing that something could be done to vivify the interest in our noble science. There is no branch of so much practical usefulness upon which there is such probable ignorance in the profession as this. Further, when you think that chemistry, physiology, etc., may be conducted and studied at a distance, but human anatomy only in the medical school, the need of stimulating the student to use all his efforts to avail himself of opportunities, which assuredly for the majority will never come again, is most imperative. The remedy is not far to seek. The same methods so successful elsewhere have not been, but should be, applied to the study of anatomy.

The classes should be divided into small sections for the "bedside study" of the cadaver. Skilled instructors who make this a specialty should be continually at the elbow to encourage, direct, and drill. A demonstrator of anatomy should not be a practitioner, but a specialist spending his whole time in the rooms and saturated with the anatomical atmosphere. No one can fulfill the office of a teacher who is not filled full of his subject. The hours of the sections for histology or hygiene are fixed and certain; and so should it be here, and not left to an elastic sweet will, which too often does not will to go at all.

The anatomical room should properly be in a building by itself, of but one story, easy of access, so that it may be the haunt of the pupil when not otherwise engaged, or when an empty one-fourth hour should tempt to the speedy elucidation of some single point. There should be ample facilities for instruction—strike while the iron is hot, is the right principle. I will guarantee that a specimen, well worked out, placed in the hands of a student while engaged upon a given part, is ten times the worth to him that it is when held up at the distance of 20 feet in the midst of a formal lecture, or when kept high upon the sacred shelf of the medical museum. The museum in a medical school is usually of comparatively little use. Each dissecting room should have its own collection of moist and dry specimens in jars or in cases of ready access when the student may be most interested, and therefore most needs it. This dissection is a two-headed Janus (for we must dissect in order to know), yet in order to dissect intelligently we must have some foreknowledge, and this paradox is best solved by the study of the moist and dry preparations which the student should be encouraged to examine, both before and after, as well as during the procedure of dissection.

Then, the instruction should be direct and personal. It is here, as in everyday life—the greatest philanthropist is not he who helps many wholesale or insists upon the unfortunate doing his way, but rather the one who kindly helps when help is needed, and without protrusion of self gently lifts the fellow out of the rut of wrongdoing. "A friend in need is a friend indeed," implies that the proper aid is given just at the time required, not before. Demonstrations therefore should be personal and upon the cadaver, not a mere recital of facts. Class demonstrations are useful particularly for a rapid résumé to the more advanced student, but the speechmaking should be subsidiary to the demonstration of structure. An ideal method perhaps would be to encourage each student to carefully prepare and preserve his own dissections, as thereby would be acquired a stimulus to more careful work, and then at the time of demonstration each would have in his hands a dissection upon which to follow the explanation of the teacher.

I have spoken of the emphasis laid upon the examination after the lecture course. This is only a means to an end, but to the majority it is the *ultima Thule*. It would be far better to exact an examination upon each dissection and at the end of the course a finality upon the cadaver.

I have already disclaimed any intention of detracting one iota from the value of lectures, but really how opportune if the phonograph could be utilized for this purpose. Let the most able and scientific of this society write out a series of lectures which could be spoken into the instrument by the most eloquent member. Then a tyro could turn the crank and deliver to a delighted audience the most perfect of courses and these could be multiplied indefinitely so that each medical school could be supplied on demand, while thereby could be secured that uniformity of nomenclature which has harassed the minds and hearts of our members for a considerable season.

There is one other point I wish to touch upon. (1) The absence of systematic records of anomalies and pathological lesions which would be of extreme value if properly noted, and the waste of magnificent material yearly in all of the schools which could readily be utilized for scientific purposes. Think you a dissecting room is only to study anatomy? There is a wealth of pathology, a richness of surgical knowledge, a treasure of medical story, a mine of anomalous relations, all gone, burned, or buried. Like the early miner of the West, in our haste and with our careless or crude methods, we overlook the very gold we fain would grasp, and some more careful worker will enrich himself and his race from the waste which we throw away. I have endeavored to point out some of the more glaring defects in the anatomical room which stand in the way of its improvement.

(1) It is subordinated to the lecture method which, rightly, should be subordinate to it.

(2) It is too often repulsive and inaccessible.

(3) It is not managed with precision that find in other departments.

(4) The teaching facilities are rarely what they should be, and should be supplemented by an extensive museum, ready of access under proper regulations to the student, who should be allowed to handle the specimens himself.

(5) The teaching should be personal and demonstrative rather than didactic.

(6) The test should be one of practical knowledge of the cadaver, rather than of merely theoretical data.

(7) A proper record of all anomalies and pathological lesions found should be kept, and the invaluable specimens added to the teaching facilities of the various departments of the school.

---

### THE HUMAN HAND.

By GEORGE WILLIAM WEAR, M. D., of Washington, D. C.

The human body is one of the most worthy objects of man's study. It is the noblest as well as the crowning work of creation. In it material organization is carried to the greatest perfection. There is no part of the human body which is more significant in its actions, which is more characteristic in its formation than the hand. One of the first points which obtrude themselves upon the student of anatomy is the absolute perfection of the human hand as regards its construction and the uses to which it is adapted. In no other combination of bones, muscles, and nerves, and in no other animal do we find a perfection which results in such superiority with regard to strength, variety, extent, and rapidity of motion; and this perfection undoubtedly resulting from the intimate relations which exist between the hand and the intellect, we are irresistibly to ask with Sir Charles Bell: "Is it nothing to have our minds awakened to the perception of the numerous proofs of design which present themselves in the study of the hand, to be brought to the conviction that everything in its structure is orderly and systematic, and that the most perfect mechanism, the most minute and curious apparatus, and sensibilities the most delicate and appropriate, are all combined in operation that we may move the hand?"

As Galen remarks: "Let us then scrutinize this member of the body and inquire, not simply whether it be in itself useful for all the purposes of life, and adapted to an animal imbued with the highest intelligence, but whether its entire structure be not such that it could not be improved by any conceivable alteration." The wants of man are greater and more varied than those of any other animal; therefore, he has had given to him what he alone of animals possesses, and what to him alone is necessary, viz, the hand. The genus homo, or man, takes rank in the classification of mammals as a distinct order, Bimana, in consequence of man being the only animal possessing two hands. At first sight, it might be considered that four-handed animals, the monkeys, apes, and their allies which are placed by zoölogists in the order Quadrumana, were superior to those which possess only two hands, but this is far from being the case. None of these four hands are adapted to the variety of actions which the human hand is capable of performing, and they are all to some degree, required for support and locomotion; so that while in the higher forms of the quadrumana the extremities present an approximation in structure to those of man, in the lower they gradually tend to resemble the ordinary quadrupedal type. "That," says Cuvier, "which constitutes the hand, properly so called, is the faculty of opposing the thumb to the other fingers, so as to seize upon the most minute objects, a faculty which is carried to its highest degree of perfection in man, in whom the whole anterior extremity is free and can be employed in prehension."

The peculiar prehensile power of the human hand is chiefly dependent upon the length, power, and mobility of the thumb, which can be brought into exact opposition to the extremities of all the fingers whether separately or grouped together. Some animals are bold and fierce, others are timid and gentle, some are gregarious and coöperate for their mutual sustenance and defense; others are solitary and avoid the society of their fellows; but all have a form or body accommodated to their natural dispositions and habits. Thus, the lion has powerful fangs and claws; the hare has swiftness of foot, but is otherwise defenseless. And the fitness of this arrangement is obvious; for those weapons which the lion is furnished with are as appropriate to his nature as they would be inappropriate to the timid hare, whose safety, depending entirely on flight, requires that swiftness of foot for which she is so remarkable. But to man, the only animal that partakes of divine intelligence, the Creator has given, in lieu of every other natural weapon or organ of defense, that instrument, the hand, an instrument applicable to every art and occasion as well of peace as of war. Man, therefore, wants not a hoof or a horn or any other natural weapon, inasmuch as he is able with his hand to grasp a much more effective weapon, the sword or the spear; for a sword or a javelin are better arms than the nails, and cut and pierce more readily. Besides which, natural weapons can be employed only in close conflict, while some of the weapons employed by man, such as javelins or arrows, are even more effective at a distance. He is enabled more easily by this instrument to clothe himself with armor of various kinds or to intrench himself within camps or fenced cities, whereas were his hands encumbered with any natural armor, he would be unable to employ them for the fabrication of those instruments and means which give him such a decided advantage over all the other animals of creation.

With the hand we weave the garments which protect us from heat and cold in summer and winter, and construct the nets and snares with which we subjugate the brute creation. With the hand we fashion all the implements of art and science, and, lastly, by means of the hand man bequeaths to posterity in writing the intellectual treasures of his own divine imagination; and hence we who are living at this day are enabled to hold converse with Plato and Aristotle and all the venerable sages of antiquity. Thus the hand keeps constantly before us the proofs of the special adaptions of the various parts of the body to the uses to which the parts are to be put. "In man," says Prof. Owen, "while one pair of limbs is expressly organized for locomotion and standing in the erect position, the other pair is left free to

execute the manifold behests of his rational and inventive will, and exquisitely organized for delicate touch and prehension, emphatically called manipulation." The hand is essentially the organ of the mind, the medium of its expression, and the instrument whereby its promptings are carried into execution. "We first see the hand," says Sir Charles Bell, "ministering to man's necessities and sustaining the life of the individual; in a second stage of his progress we see it adapted to the wants of society, when man becomes a laborer and an artificer; in a state still more advanced, science is brought in aid of mechanical ingenuity, and the elements which seem adverse to the progress of society become the means conducing to it." The seas, which at first set limits to nations and grouped mankind into families, are now the means by which they are associated.

Before entering further into the description of the hand, it is necessary to say a few words on the upper extremity generally, of which the hand may be regarded as the essential part. The general plan of the osseous framework of the upper and lower limbs is very similar. The humerus, or arm bone, corresponds to the femur, or thigh bone; the lower end of the humerus is connected with the two bones of the forearm, the radius and the ulna, which correspond with the two bones of the leg, the tibia and fibula. Then come the carpal bones, the metacarpal bones, and the phalanges, just as we have tarsal bones, metatarsal bones, and phalanges in the foot. It is not necessary to enter into any anatomical details regarding the individual carpal bones. Collectively they are so arranged that the carpus presents a dorsal convex surface, upon which the tendons of the extensor muscles of the fingers play, and a palmar concave surface, on which the tendons of the flexor muscles lie. The several bones are joined to one another, each bone being united to three or more others by a large extent of surface, and are girded together by strong ligamentous bands. The wrist is thus as strong as if had been constructed of one solid piece of bone, while the slight gliding movements which occur between the several bones give it an elasticity which serves to break the shocks that result from falls upon the hand. The uppermost surface of the first row of carpal bones is convex, and this convex surface is received into a wide cup, or socket, formed by the lower articular surface of the radius and by a ligament passing from that bone to the ulna. The metacarpal bones and the phalanges require no special description. Like the great toe, the thumb has only two phalanges, while each of the other digits has three. The scapula, or shoulder blade, with which the principal arm bone articulates, is itself movable to a considerable extent on the surface of the ribs, on which it rests. Again, the socket in which the nearly spherical head of the humerus, or arm bone, lies is very shallow, not unlike the cup in the well-known toy cup and ball, and the arrangements of the shoulder joint generally are such as to permit so great a variety and so extensive a range of movements that we are able to apply the hand to every part of the body. This freedom of motion is due in a great degree to the clavicles, or collar bones, which, by steadying the shoulder blades and keeping the shoulders apart, afford a fixed point for the various muscles which we employ in raising the arms, in folding them over the chest in the act of hugging, or in the attitude of prayer. The movement of the next junction of bones, the elbow joint, are very different from that at the shoulder. The latter is termed, from its construction, a ball-and-socket joint, and admits of motion in all directions, within definite limits, while the former is a hinge joint, and merely admits of bending and straightening, or, in other words, of motion in one plane.

A full consideration of the muscles of the hand would take too much time. We may demonstrate upward of fifty muscles of the arm and hand, all of which must consent to the simplest action. Nothing appears to us more simple than raising the arm or pointing with the finger; yet, in that simple act, not only are innumerable muscles put into activity, and as many thrown out of action, but both the relaxing and the contracting muscles are controlled or adjusted with the utmost precision, though in opposite states, and under one act of volition. To the anatomical student, the mode of demonstrating the muscles of the human hand and arm becomes

the test of his master's perfection as a teacher. When they are taken successively, just as they present themselves in the arm, nothing can be more uninteresting, tedious, and difficult to attend to than such a demonstration; but when they are taught with lucid arrangement, according to the motions performed by the distinct groups of muscles, it is positively agreeable to find how much interest may be given to the subject.

Just here we will consider a class of movements of the forearm and hand, to which there is nothing analogous (at least to any material extent) in the leg. The movements in question are called pronation and supination. In pronation (derived from *pronus*, with the face downward) we turn the palm of the hand downward, as in picking up any substance from the table; in supination (derived from *supinus*, with the face upward) we turn the palm upward, as for the purpose of receiving anything that may be placed in it. These movements of pronation and supination are so important to the usefulness of the hand that it is necessary to notice the three muscles by which they are chiefly produced. One of the three muscles passes from a projecting process on the inner side of the humerus, at its lower end, to the outer edge of the middle of the radius. Its contraction causes the radius to roll over, or in front of, the ulna; it thus pronates the hand, and is called a pronator muscle (*pronator radii teres*). Another muscle passes from a projecting process on the outer side of the humerus to the inner edge of the radius near its upper part. It runs, therefore, in an opposite direction to the former muscle, and produces an opposite effect, rolling the radius and the hand back into the position of supination; hence, it is called a supinator muscle. The third is a very powerful muscle, termed the biceps, which not only bends the elbow, but from the mode in which its tendon is inserted into the inner side of the radius, also rotates the radius so as to supinate the hand, and it gives great power to that movement. Mechanics have observed that they have more power to supinate the hand than to pronate it. Supination can only be performed to its full extent by man, and even in man it is not the natural or habitual position; monkeys can partially effect the movement, and in most of the lower animals the part corresponding anatomically to the hand is constantly in a state of pronation.

The movements of which the hand itself, without reference to the arm, is capable, are very numerous, and in this respect differ considerably from the corresponding movements of the foot. Thus the fingers can be bent down upon the palms or they can be extended beyond the straight line; they can be separated from one another to a considerable extent, and they can be closed with considerable force. The wrist and hands are bent forward, or flexed, upon the forearm by three muscles which pass downward from the inner condyle of the humerus, and are termed the radial flexor, the ulna flexor, and the long palmar muscles. The first two of these muscles are inserted into the wrist bones on the radial and ulna sides, respectively, while the third expands into a fanlike fascia, or membrane, in the palm of the hand, and thus serves both to support the skin of the palm and to protect the nerves and vessels which lie below it. Beneath the palmar fascia lie two sets of flexor muscles of the fingers, and they present so beautiful a mechanical arrangement as to merit special notice. The superficial or perforated flexor muscle passes down the front of the forearm and divides into four tendons, which becomes apparent after removing the palmar fascia, and are inserted into the second phalanges of the fingers, each tendon splitting at its termination, to give passage to the similar tendons of the deep or perforating flexor muscle, which passes from the upper part of the ulna to be inserted into the last phalanx of each finger. These flexor muscles are antagonized by the common extensor muscle of the fingers, which, like the flexors, divides into four tendons, one for each finger. Besides these, there is a special extensor of the index finger, a series of muscles forming the ball of the thumb, which move that organ in almost every direction, and various small slips giving lateral and other movements to the fingers.

The hand contains two principal arteries, the radial and the ulnar. The ulnar proceeds in a curve from the wrist to the first finger where it joins a branch of the radial, forming what is known as the superficial palmar arch. Four digital arteries go from its convexity, which subdivide into collateral branches about two lines below the metacarpo-phalangeal articulations. These supply the palmar and lateral surfaces of the fingers, excepting the thumb and the outer side of the index, the branches coalescing at the tips of the fingers, whence branches arise to supply the pulp of the fingers with blood. The radial goes from the end of the forearm (radius) round the wrist, between the thumb and index finger, and back into the palm, where, joining the ulnar, it forms what is known as the deep palmar arch. Before, however, it does this, it gives off two arteries, one of which (the *superficialis volæ*) supplies the palm, whilst the other divides into two branches (the *arteriæ dorsales pollicis*) which run along either side of the thumb, one of which branches sends off an artery to the index finger. When the radial dips into the palm it gives off branches to the thumb and forefinger or index, and to the deep palm (where it joins the ulnar). The veins, which are generally very deep, accompany the arteries.

The most important subject for our consideration is that of the nervous system of the hand, of that complicated plexus of nerves which gives to the hand its direct and constantly apparent connection with the brain. Without the hand, principal seat as it is of the sense of touch, the other senses would be comparatively useless. The sense of touch is the only sense which is reciprocal. That is, though the senses of sight, hearing, taste, and smell, can only receive impressions without giving them, that of touch, both receives and gives; and it is this sense of touch, dependent as it is upon the nervous system, which is the most important of all, and which is found in its highest state of development where that nervous system is the most complete, namely, in the hand.

An accumulation of fat and fibrous tissue under the skin forms the "pulp" at the ends of the fingers. The slightly conical form and exquisite softness of the pulps adapts them well for the examination of the surfaces of bodies; and the sense of touch is more acute in them than in other parts of the hand. In connection with them it is interesting to observe that the last bone of each finger and of the thumb swells out at the end into a nodulated lump, which serves the purpose both of supporting the pulp and of giving breadth to the nail. The cuticle is the medium through which the external impression is conveyed to the nerves of touch. The extremities of the fingers exhibit all the provisions for the exercise of this sense. The nails give support to the fingers; they are made broad and shieldlike, in order to sustain the elastic cushion which forms their extremity. This cushion on the end of the finger is a very important part of the exterior apparatus, its fullness and elasticity adapting it admirably for touch. Fine as the sense of touch usually is in the hand, it becomes far more so when an unusual demand is made upon it in consequence of a deficiency or absence of other senses. The rapidity with which blind persons can read with their fingers is truly astonishing. Some are said to distinguish colors by the feel. It should rather be said that they are capable of recognizing the nice differences in certain substances by which colors are caused; for one can scarcely conceive it possible to distinguish by feeling the colors in a ray of light separated by a prism.

It was said of a lady who had been not only blind but deaf and dumb from infancy:

"The sense of touch was, therefore, almost her only avenue for impressions from without, and it was surprising how much information was conveyed through it, and how quickly. It enabled her to hold converse with her relatives, by the language of the fingers, almost as freely and as briskly as others did with the tongue. A few touches were sufficient to transmit a series of thoughts. After one shake of the hand of a stranger she would immediately recognize him on meeting him again."

Persons who have had much experience in the instruction of the deaf and dumb find that the hand, by means of writing and "dactylology," or the language of finger signs, is abundantly sufficient for all the intercourse to which a deaf-mute is equal;

and they are, therefore, disposed to discourage the teaching of articulation. The capacity, therefore, which the hand enjoys of ascertaining the distance, the size, the weight, the form, the hardness or softness, the roughness or smoothness of objects, results from its having a compound function, from the sensibility of the proper organ of touch, being combined with the consciousness of the motion of the arm, hand, and fingers. But it is the motion of the fingers that is especially necessary to the sense of touch. These bend or extend, or expand or move in every direction, like palpa, with the advantage of embracing the object, feeling it on all its surfaces, estimating its solidity or its resistance when grasped, moving round it, and gliding over its surfaces, so as to feel every asperity and be sensible of every slight vibration.

Why is man usually right-handed? Many attempts have been made to answer this question. Is the superiority of the right hand real and natural, that is, congenital, or is it merely acquired? All men are not right-handed; some are left-handed; and some are ambidextrous. In the tribe of Benjamin "there were seven hundred chosen men left-handed; every one could sling stones at an hair breadth and not miss." (Judges xx, 16.) When David was at Ziklag there came to him a company of men who "were armed with bows and could use both the right hand and the left in hurling stones and shooting arrows out of a bow." (1 Chronicles, xii, 2.) There is an universal consent among all nations to give the preference to the right hand over the left. This can not be a conventional agreement; it must have a natural source. For the convenience of life, and to make us prompt and dexterous, it is pretty evident that there ought to be no hesitation which hand should be used, or which foot should be put forward; nor is there, in fact, any such indecision. Is this readiness taught, or is it given to us by nature? It is suggested that if the right side were originally the most powerful in man, we might expect to find it the same in other animals. It is affirmed that squirrels, monkeys, and parrots feed themselves with the left leg rather than with the right. But the parrot may be said to use the strongest foot where most strength is required; that is in grasping the perch and standing, not in feeding itself. It must be observed at the same time that there is a distinction in the whole right side of the body as well as in the arms, and that the left side is not only the weaker in regard to muscular strength but also in its vital or constitutional properties.

The development of the organs of action and motion is greatest upon the right side, as may at any time be ascertained by measurement or the testimony of the tailor or shoemaker. Certainly this superiority may be said to result from the more frequent exertion of this side; but the peculiarity extends to the constitution also; and disease attacks the left extremities more frequently than the right. In walking behind a person it is seldom that we see an equalized motion of the body; and if we look to the left foot, we shall find that the tread is not so firm upon it, that the toe is not so much turned out, and that a greater push is made with the right foot. The horseman puts the left foot in the stirrup and springs from the right. We think we may conclude that the adaptation of the form of everything in the conveniences of life to the right hand, as for example, the direction of the worm of the screw, or of the cutting end of the auger, or the shape of other tools or instruments, is not arbitrary, but is related to a natural endowment of the body. On the whole, the preference of the right hand is not the effect of habit, but is a natural provision, and is bestowed for a very obvious purpose; the preference is given to the right foot as well as to the right hand.

---

#### DISCUSSION.

Dr. Lamb said that the general opinion seems to be that the left side of the brain appears to be better supplied with blood as a consequence of the arrangement of the branching of the arch of the aorta. As a consequence of this greater development of the left side of the brain, we have the greater development and use of the right upper extremity. It may be well to notice in this connection the fact that in very

many cases there are eight costal cartilages connecting with the sternum on the right side, giving, therefore, a greater support to the right upper extremity.

Dr. Lamb has recently made a post-mortem examination of a woman who was left handed, and there were eight cartilages on that side connected with the sternum.

Dr. Reyburn stated that in all probability the larger supply of blood given to the right upper extremity will account for its greater development. The great difficulty in this matter is the want of text-books on anatomy written from the standpoint of studying human anatomy as the development from the human brain; but it will be done soon by someone, and the book will render his name immortal.

Dr. Baker remarked that the dextral preference had been variously explained as due to the position of the fœtus in utero, the position of the vessels on the arch of the aorta allowing a greater supply of blood to one side of the brain than to the other, etc. The most plausible theory that has been urged seems to be that it is derived from the necessity which primitive man found to protect his left side. The left arm becomes the shield or defensive arm, the right the spear or offensive arm. This necessity, continued through countless generations, has caused the differentiation.

Dr. L. S. Pilcher, Brooklyn, N. Y., said:

The Chair remarked that he had hoped to hear some reference on the part of the eminent members of the section upon the relations of the development of the cerebral centers which govern the actions of the hand to the question of dextral preference. It seemed to him that in the laws of cerebral development was to be found the explanation of this phenomenon. He did not think there was any substantial difference in the nutrition of the two sides of the brain, due to the slight differences which measurements had shown to exist in the respective capacities of the blood vessels on the two sides of the neck that transmitted blood to the cerebrum; the freedom of anastomosis that existed within the cranial box favored the uniform diffusion of the blood that was brought to the brain. Nevertheless, he believed that an earlier or more complete development of the centers in the left brain occasioned the more perfect and constant use of the right upper extremity in the various affairs of life. The reflex effect of such preponderating muscular work upon the further development of the nerve-centers that controlled them was a well recognized fact, and from this had been drawn the practical recommendation to begin, at an early date, to exercise the left as well as the right upper extremity, so that the possibilities of disaster in later life from possible degenerations of the developed side might be guarded against by the more equal development of both sides. He invited discussion on this phase of the subject.

## LAWS OF THE GROWTH OF THE CELL APPLIED TO HUMAN ANATOMY.

By ROBERT REYBURN, A. M., M. D.

*Professor Physiology and Clinical Surgery Medical Department, Howard University, Washington, D. C.*

The human ovum or egg, from which all the tissues and organs of the human body are built up, is in the earliest stages of its embryonic life nothing more or less than a simple cell or mass of protoplasm. These cells or masses of protoplasm are practically identical in all animals and consists, after impregnation, of a fecundating living germ, which has surrounding it a limited supply of food yolk or nourishment, which serves to nourish the embryo until other structures are developed, which carry on the process of nutrition during the entire period of fœtal existence.

As the human ovum is directly transformed during its process of development into the human body, it is obvious that the laws governing the growth of the ovum must furnish the key to the growth of the human body in its adult or completed form. What, then, are these laws, or rather the causes or conditions, which modify the growth of the cells composing the body? The first of these conditions is that cells,

when young and growing, increase in size by layers of nutriment deposited upon the outer surfaces of the cells, accompanied by a nearly equivalent amount of the waste products of the cell, which is absorbed from its inner surface. So long as the amount of nutritive material deposited upon its outer surface is greater than the waste from the inner surface, the cell continues to grow and increase in size until the time of maturity is reached. At this point the forces of waste and destructive assimilation are just balanced by the powers of the organism to absorb and assimilate nutriment.

After this period is reached the individual cells (and in consequence the body as a whole) gradually cease to absorb and assimilate as much of nutritive material as is required to supply the waste, and hence the result of inevitable death, which is the pitiless law that rules the organic world. How, then, does the human body as a whole grow from infancy to maturity? Precisely in the same way as the individual cells of the body do. Take, for instance, the development of the aorta, the great arterial trunk of the body. In the new-born child the aorta is a tube the lumen of which will measure perhaps three-eighths of an inch across; when this same child has reached adult manhood, his aorta will have become a great tube an inch or more in diameter. This increase in size, it is very evident, must have been produced in the way above described. As years pass on numberless layers of microscopic tenuity have been piled up upon its outer surface, thus increasing the thickness of its walls. Along and simultaneously with this process goes on the absorption from the inner walls of the waste tissue, thus increasing its dimensions both externally and internally. This same law of growth is applicable to the development of the intestinal canal with the stomach and accessory organs of digestion, to the growth of the Haversian canals and medullary cavities of bone, to the growth of the shafts of the long bones of the extremities of the body, and, indeed, to the growth of the limbs in their entirety. Not only is this law of growth true of every organ and structure found in the body, but it is just as true when applied to the growth of the human body as a whole.

The second of the causes which modify the shape of the living cells of the body is their tendency to grow towards the source of nutriment. Living cells when free or floating in the liquids of the body are always more or less circular in shape. As found in other parts of the body, they are very variable in size and form. Take, for instance, the cells in the lacunæ or the bone cells; these were originally circular or ovoidal cells. As the process of transformation of cartilage into bone, for instance, goes on, these cells gradually become incased by layers of earthy matter surrounding them, which would prevent the absorption of the pabulum necessary for their nourishment. In order to overcome this difficulty the cells in their process of growth absorb certain portions of the walls inclosing them, and thus the myriads of canaliculi, or fine tubes, which connect the bone cells with each other, and the Haversian canals are formed. The canaliculi are of course entirely too small to admit the entrance of the red or white corpuscles of the blood, or even the blood plaques of Bizzozero, and their nourishment is maintained by the liquid plasma of the blood. Many illustrations of this second cause are to be found in the body. It is only necessary here to mention the rapid repair of fractures of the long bones, when the fracture occurs just below the point where the nutrient artery enters the bone, as compared with the slowness of repair when it occurs just above (thus partially cutting off the circulation of blood in the part). In fact, it is universally admitted that the growth and development of every organ and tissue in the body is directly proportioned to the amount of its blood supply.

The third cause modifying the form of the cells of the body is that each cell and the body as a whole tend to reproduce, under favorable conditions, the same type of the parent cell from which it sprang. Bone tends to reproduce bone. Muscle reproduces muscle, and so, in like manner, do all the tissues and organs of the body.

In pathologic growths we do find alien and foreign tissues in the diseased portions of the body. Bone, for instance, is often found in epidermoid cysts, and in parts of the body which in health are composed of cartilage and muscle.

One important fact, however, is to be noted in studying the constituents of pathologic growths, and that is that all pathologic growths are histologically true to the class of tissues generated by the layer of the embryo from which they were originally formed. As is well known the human embryo primarily divides into two layers, the ectoderm or epiblast and the endoderm or hypoblast. A third layer is afterwards developed between these which is called the mesoderm or mesoblast. Tissues, therefore, which originally sprang from the first two primary layers of the embryo, do not tend to reproduce the tissues which are formed from the mesoderm or middle layer of the embryo. The exceptions to this rule are rare.

The fourth cause or condition, modifying the shape and growth of cells, is the pressure of other cells upon them during the early period of their growth. The multiform shapes of the cells found in cancerous tumors are evidently due to this cause, as well as the flattened shape of the cells found in the epidermis, hair, and many other parts of the body.

After maturity, the retrograde change or metamorphosis at once begins in the cells, and as a necessary consequence in the body as a whole. The powers of assimilation of nutriment gradually become insufficient to supply the waste, and hence the body as a whole tends to emaciate. Not only is this the case, but the power of the individual cells to separate the waste materials which are the results of their nutrition, become impaired. These waste materials of the cells as a consequence accumulate and cause thickening of the cell walls of all parts of the body. One of the most striking of the results of this process is seen in the hardening and calcification of the arteries of the body, which is so commonly found in persons of advanced age. The tissues themselves tend to degenerate in old persons. Muscle becomes degraded into fat, and the same degenerative process invades the connective and other tissues of the body. A familiar example of this is to be found in the arcus senilis, which is a sure sign of the degeneration of the tissues.

It may seem, perhaps, necessary to apologize to an audience like this for such an elementary sketch of the growth and development of the human body. My object in doing so has been to call attention to what I believe to be our unscientific method of teaching human anatomy, as it is usually taught in our medical schools and colleges. The most usual or ordinary method of teaching human anatomy is to begin by studying the bony framework of the adult human body. This has always seemed to add unnecessary complexity to the study, and prevents the student from grasping the real simplicity of the idea of the structure of the human body when studied from the point of view of its being simply a development from the human ovum or cell. The study of the various organs of the body also is much better commenced by examining them, with the aid of the microscope, as the same organs are found in the lower order of animals. The kidney, for instance, in man is quite a complicated organ, many of the parts of which it is difficult for the student to understand. In the common newt it is composed simply of a layer of tubes which can be studied and comprehended by the student with comparative ease. What is our plan in pursuing other studies? If we, for instance, take up the study of chemistry, we never begin by studying the complex compounds first; on the contrary, we first study the elements out of which the complex bodies are formed, and thus proceed from simplicity to complexity. The same method is adopted if we take up the studies of botany, geology, mineralogy, or, in fact, any of the branches of natural science. Why, then, do we adopt a different method in the study of human anatomy from the one we adopt in studying all the other branches of science? My idea of the true way to study human anatomy, then, would be to begin by studying the human ovum or cell, then the fluids, such as the blood and lymph in which the cells are found free and floating. After this study the changes produced in the ovum by impregnation, the segmentation of the ovum, with the development of the blastodermic membrane of the embryo and its further division into the external and internal layers. Study, then, the tissues and organs formed from these layers in the order of their development. Then take up the study of the middle or third layer of the embryo, with the

tissues and organs formed from it. The study of human anatomy carried out in this way gives to it a simplicity and beauty that renders it worthy to be classed among the exact sciences.

It may be here remarked that this method of teaching anatomy is not a new or untried one. Prof. Piersol, of the University of Pennsylvania, I am informed, teaches human anatomy in a manner essentially the same to the one above described, and the writer, a number of years ago, when professor of anatomy in Georgetown University, adopted with success the same plan.

---

#### DISCUSSION.

Dr. John B. Roberts said:

The teaching of anatomy is, as the author has said, usually taught in an unscientific manner, because the complex human body is studied by students who know nothing of biology. The true method is to begin the study with simple forms, vertebrate and invertebrate.

Dr. West said:

In reply to Dr. Robert Reyburn's most able paper on laws of the growth of the cell applied to human anatomy, in which he suggests that the proper mode of teaching anatomy is to begin with the cell structure (histology or general anatomy), I agree with him perfectly, but the question comes up, under whose chair does this important branch of anatomy come. I claim that it does not come under the chair of anatomy, whose duty it is to teach descriptive and special anatomy, but it properly comes under the chair of physiology or that of normal histology, which chair every medical college should have, armed and equipped with a microscope as well as everything else pertaining to the proper teaching of that chair, which I consider as important as any other chair in a well-equipped medical college. The professor of anatomy proper, that is of descriptive and general anatomy, has just as much as he can attend to and more besides, to do justice to his subject in the short space of time (two years) given him. He would be getting into deep water to begin with such a task, covering so vast a field as it does.

#### ON THE RECENT OCCURRENCE OF *LINGUATULA RHINARIA*, RAILLIET, 1886, AND *TÆNIA ECHINOCOCCUS*, V. SIEBOLD, 1853, IN THE UNITED STATES OF NORTH AMERICA.

By CHARLES W. STILES, PH. D.

*Medical Zoologist, Bureau of Animal Industry, U. S. Department of Agriculture, Washington, D. C.*

I wish briefly to call attention to two parasites, comparatively rare in this country, found both in man and domesticated animals.

The first one, *Linguatula rhinaria* (*L. serrata*, *Pentastoma tænioides*), is by no means uncommon in Europe and has been reported several times in South America. Until recently, however, it has not been noticed in the United States. F. L. Kilborne, B. V. S., of the Bureau of Animal Industry, found eight specimens in a rabbit at Washington, D. C., several years ago (Curtice, *Journal of Comparative Medicine and Veterinary Archives*, 1892, p. 231), and Dr. Cooper Curtice found one specimen in another rabbit in this city (Curtice, *l. c.*). These two finds are, so far as I have been able to learn, the only cases on record of this parasite in North America.

Quite recently (July 3, 1893) my colleague, E. A. Schrøder, M. D. V., in making post-mortems on cattle at the Soldiers' Home, in the District of Columbia, observed a peculiar appearance of the mesenteric glands and, upon cutting them open, he discovered an organism which he suspected belonged to the species now under consideration. The parasites (forty in all) were present in three different steers. Dr. Schrøder kindly turned the material over to me for final diagnosis and I instantly confirmed his specific determination.

As the rabbits and cattle mentioned above were all raised in this region, the finding of these parasites proves conclusively that the infection took place in this vicinity, or in other words, that the adult from this parasite is present in dogs in the district. This is a point of considerable interest to physicians, since man is subject to infection by this parasite.

It is not my intention to give an exhaustive account of this subject, as the species in question has already been worked up by my European colleagues, and as I have already published on this same matter myself. As this arachnoid is, however, comparatively unknown in North America, it will perhaps be in place for me to give a very brief summary of the biology of the subject.

The specimens which I now exhibit to you measure 4 to 6 mm. in length. These represent the larval stage generally known as *Linguatula serrata* or *L. denticulata*, which is found in the liver and other viscera of herbivorous animals. It has also been found in the domestic cat. If these parasites gain access to the nasal cavities of dogs, they develop into the adult stage known as *Pentastoma tænioides*, which grows to the length of 18 to 26 mm. (male) or 70 to 130 mm. (female). The animals copulate, and the female produces an immense number of eggs, which escape with the nasal mucus of the host. Each egg contains a minute 4-legged embryo, which in turn develops into the larval stage upon being swallowed by a herbivorous animal.

The species can be recognized by the following external characters: The animals are more or less flat dorso-ventrally; they possess about thirty transverse rings; on the ventral surface of the anterior portion in the median line is situated the mouth, and on each side of the latter are to be found two hooks; the vulva is posterior, while the male opening is just caudad of the mouth.

The life history as given above is the usual and most simple cycle, but is subject to several exceptions. As I have treated these exceptions in detail elsewhere (*Sur la Biologie des Linguatules*, Compt. rend. de la Soc. d. Biologie, Paris, 1891, p. 348), I will note here only one or two cases which seem to me the more important from the standpoint of the practitioner.

In cases where men have harbored this species, it seems incontestable that the infection has generally taken place in one of the following ways: (1) By obtaining the embryos directly from dogs infested with the adult form; (2) by swallowing embryos with the drinking water; (3) or by eating vegetable food which has been soiled by the nasal discharge of dogs.

All authors seem to agree upon these three modes of infection. Personally I have suggested a fourth (*loc. cit.*) mode of infection, based partly upon theoretical grounds, partly upon observations and experiments with an allied species (*Procephalus crotali*; *Pentastoma proboscidium*). If larval forms of this latter species are fed to snakes, some of the specimens reach the lungs, while others simply bore through the intestinal walls and become encysted in the body cavity. Theoretically the same must apply to *Linguatula rhinaria*, that is, if a man should eat a piece of liver or other organ containing living specimens of this species, it is perfectly possible that some of the parasites would bore their way to the abdominal cavity and be found later in that place.

Carrying the matter further, I prophesied two years ago (*loc. cit.*) that *Procephalus crotali* would one of these days be found as a parasite in the opossum (*Didelphys virginiana*), and as a chance parasite in the American negro, the latter receiving his infection from eating the opossum. The first part of my prophecy has already been fulfilled, for my assistant, Dr. Hassall, and I have recently found this parasite in several opossums, and Leidy some years ago made a similar find, which was not known to me at the time I wrote the article referred to.

I can hardly leave this subject without referring to Babes' theory in regard to the wanderings of *Linguatula rhinaria* in cattle. He believes that the parasites bore from the abdominal cavity into the lumen of the intestines, are expelled with the fæces, and are afterwards taken up from the ground by dogs. As I have stated elsewhere, this seems perfectly possible, but certainly can not be looked upon as the

general mode of infection, for I have convinced myself by repeated experiments that the larval tongue-worms may develop in the intestinal wall. Now, when they burst their cysts, they will unquestionably fall into the abdominal cavity, or into the intestine, according to the direction of least resistance.

The second parasite to which I wish to call your attention, is *Tænia echinococcus*. It is well known to you that the larval stage (*Echinococcus polymorphus*) of this parasite is more or less common in certain countries, and that a number of cases have been reported in man in this country. Most of the cases found in man in this country have, however, been in foreigners. We have also four cases on record of its occurrence in American hogs (Welch 3, Moore 1), and one case in cattle (Stiles). These cases in domesticated animals, as well as the cases in Americans who have never left the country, demonstrate that the adult tapeworm is present (though rare) in American dogs; in fact F. L. Kilborne has found it in one dog in this city (Curtice, *l. c.* p. 231).

Quite recently reports have come to me that the echinococcus hydatid is very prevalent among Texas cattle, and surprise has been expressed that it has not been found more frequently in man in that State. It is in order to explain this apparent inconsistency that I mention this parasite at present.

Within the past two months I have had no less than 30 cases of this "Texas echinococcus" referred to me, and I have personally examined no less than 5,000 Texas cattle for this species, and after a most thorough study of the various specimens diagnosed as echinococcus hydatids I can state positively that not a single one of the cases I have examined represents an echinococcus.

The pathologic specimens have, indeed, a superficial resemblance to the parasite in question, but when opened are found to be abscesses.

At the request of Dr. V. A. Moore, I made bacteriologic cultures from the abscesses, and we may expect from him a report on the exact nature of the trouble. In the meantime we can rest assured that the reported prevalence of echinococcus hydatids in Texas cattle is greatly exaggerated and that we have no reason to fear that this parasite will become prevalent among the inhabitants of that State. By this, of course, I by no means state that there are absolutely no cases of this parasite in that region. I only say that none of the cases referred to me under the diagnosis given represented hydatids.

---

#### A NOTE ON THE OCCURRENCE OF THE SCAPULO-CLAVICULAR MUSCLE.

By ROBERT ORTON MOODY, B. S., of New Haven, Conn.

Last January at Yale Medical College, while dissecting the left shoulder of a male subject, I found this anomalous muscle, the scapulo-clavicular. A careful study of the literature on the subject of muscular anomalies revealed the fact that the recognized occurrence of this muscle is very rare. I could discover no record which showed that the muscle had ever been found in this country.

Dr. L. Testut, in his excellent work entitled *Les Anomalies Musculaires Chez L'Homme*, describes its occurrence in two subjects. He says it also has been described by Wood and Gruber, and that its occurrence has been noted by Luschka, MacWhinnie, and Hallet. So careful an observer as Macallister declares that he has never found it.

The scapulo-clavicular muscle is an incomplete form of the sterno scapular muscle, which, anomalous in man, is constant in many species of vertebrates, reaching its highest development in the Pachyderms and Ruminants, notably the hippopotamus, the elephant, the pig, the donkey, and the horse.

If the clavicular attachment of the scapulo-clavicular muscle were prolonged a few centimeters mesiad (toward the median line), it would become a sternal or costal insertion, and the muscle would then be a complete form of the sterno-scapular muscle.

Muscles homologous to the scapulo-clavicular muscle in man are found in a large number of mammals. Wood has found this muscle well marked in the rabbit and the Guinea pig. Cuvier and Lorillard have figured it in their atlas under the name of "scapulo-clavien."

The muscle which I found was 7 centimeters in length. Its diameter in its fleshy portion was about the same as the diameter of the fleshy portion of the posterior belly of the omo-hyoid muscle in that subject. It took its origin from the superior border of the scapula by a tendinous margin, in common with the attachment of the internal portion of the posterior belly of the omo-hyoid, and by a slender tendon, which was continuous with this tendinous margin, and which extended mesiad to within 1 centimeter of the superior angle of the scapula. In its scapular two-thirds it was internal to and parallel with the posterior belly of the omo-hyoid. At the junction of the scapular two-thirds with the clavicular third, it passed beneath the omo-hyoid muscle and continued parallel with the posterior surface of the clavicle to be inserted by a well-marked tendon into the clavicle at the junction of the posterior border with the rhomboid impression.

It is in relation dorsad, or internally with the suprascapular artery and nerve, the serratus magnus muscle, the axillary artery and vein, and the brachial plexus; superficially with the omo-hyoid muscle and the clavicle.

#### THE VERMIFORM APPENDIX.

By R. H. PLUMMER, A. M., M. D., M. R. C. S., of England.

*Professor of Anatomy, Cooper Medical College; Chief of the Surgical Clinic and of the Genito-Urinary Clinic, Cooper Medical College, San Francisco, Cal.*

The field for anatomical literature is so limited by the fixed laws of nature, and so well have these been conned, that ground for new material is found only in deviations from the usual type, which curtails the work in this department.

Not many years since health statistics teemed with reported cases of so-called "idiopathic peritonitis," but the cause became more apparent as post-mortem examinations revealed, in many cases, suppuration, perforation, or gangrene in the vermi-

form appendix, sometimes with a stercolith (coprolith) or some foreign substance, as the seed or stone of fruit, lodged therein. This knowledge has invested the appendix with new interest to the surgeon, the chief points of which are, first, its form and attachments; second, its situation and relations, having reference to operative measures. It is usually described as a "blind, worm-like tube" arising from the inner and posterior part of the cæcum, near the ileo-cæcal valve, passing thence upward and inward behind the cæcum. Extended observations, however, have demonstrated that its form and attachments vary not a little. It may arise from the posterior, the internal, or the anterior surface, or from the apex of the cæcum, the longitudinal muscular bands which characterize the large intestine being continued upon it. In some of the latter cases it appears as a funnel-form prolongation of the cæcum downward and inward somewhat as represented in the above sketch.

VERMIFORM APPENDIX.

VERMIFORM APPENDIX.

But the variation in form and attachments to which I desire to direct special attention, since I have not seen it described elsewhere, is one recently discovered in the anatomical room by one of my prosectors, Mr. Lawrence Boido. It was found to have its origin from the inner margin of the apex of the cæcum, passing thence downward and inward, crossing the brim of the pelvis, dipping somewhat into its cavity, thence ascending until it reached the ileum, about four inches distant from the cæcum, where it opened into its posterior-inferior border. It is nearly seven inches in length and about the size of a goose quill, except the last two inches, where it is dilated to about twice that size. The orifice of entrance into the ileum is somewhat constricted, but freely admits an ordinary probe.

The following sketch represents the cæcum open from the front, exhibiting the slit-like orifice of the ileum, just below which, in the apex, is the smaller opening of the appendix, showing, also, its course and attachment to the ileum.

The subject from which this specimen was taken was a German, male, laborer, sixty-two years of age, and died of pulmonary tuberculosis. So far as known he presented no history of abdominal trouble, nor was there any evidence, on post-mortem examination, of previous inflammation which might have resulted in adhesion and perforation into the ileum.

The chief interest attached to its variation in position has reference to the facility and safety of operative procedures. In 30 per cent of the large number of cases examined the cæcum has been found resting upon the psoas near its outer border on a line and midway between the umbilicus and the anterior-superior spine of the ilium. In the remaining cases it occupied various positions, viz: External to the psoas, resting upon the iliacus, lower or higher than the point above designated, or toward the pelvic cavity, reaching sometimes to, or even beyond, the median line.

The variation may depend upon the mode of development, or it may depend upon the length of the meso-cæcum, when that exists; and it is not always possible to accurately determine the position before operating. In one hundred cases examined only 26 per cent are found to have a mesentery, the peritoneum merely covering its

Stump  
slit  
down.

Trimmed  
flaps.

Flaps in-  
vaginated  
and su-  
tured.

anterior surface in the other cases. When the cæcum occupies the iliac fossa the appendix may be reached with greatest facility and safety through the ordinary semilunar incision for ligation of the external iliac artery. Frequently it will be found unnecessary to open the peritoneal cavity, thus lessening the danger by reason of the bowel being uncovered on its postero-external surface. If, however, during the operation the case be found to be one where the cæcum lies higher in the cavity, or where there is a mesentery which permits more or less movement toward the median line, it may still be readily reached by extending the incision upward and

inward toward the umbilicus. In removal of the appendix the closure of the lumen may be effectually accomplished by slitting down the sides of the stump and trimming the angular corners of the flaps, which may then be inverted or invaginated, thus bringing the serous surfaces together, where they may be sutured in position.

---

#### DISCUSSION.

Dr. Lamb said that in his post-mortem experience the cæcum was generally covered with peritoneum, except, perhaps, a portion of the posterior surface. The vermiform appendix has also been generally covered with peritoneum, of very varied length, anywhere from 2 to 8 inches, and many times twisted and angled, sometimes with adhesions. In the case of Dr. Stiles, Dr. Lamb thought that probably there had been an accumulation in the terminal portion of the sharply-bent appendix, and set up inflammation. Dr. Lamb remembered having seen but one case in which the appendix was absent. It was astonishing to notice how small an amount of disease of the appendix was apparently sufficient to cause death.

---

#### THE RELATIONS OF THE HEART AND LUNGS TO THE ANTERIOR CHEST WALL AS DETERMINED BY COMPOSITE PHOTOGRAPHY.

By IRVING S. HAYNES, PH. B., M. D.,

*Demonstrator of Anatomy in the Medical Department of the University of the City of New York, Member of the Society of the Alumni of Bellevue Hospital, of the New York County Medical Society, of the Association of American Anatomists, etc.*

The study of the relations of the heart and lungs to the anterior chest wall is of the utmost interest to us, not only as anatomists searching after the exact relations of the various parts of the human body, but also as surgeons and physicians engaged in the treatment of these organs in their various morbid states; for how can a departure from the normal relations of the body be detected unless we are familiar with those relations?

It is practically impossible to determine the surface relations of the heart and lungs in the living except in the most general way, and we are forced to study out the problem upon the cadaver. After we have obtained our post-mortem measurements we can not apply them indiscriminately to the living individual. Due allowances must be made for the constantly changing positions of the heart and lungs with every pulsation of the former and respiration of the latter, for the changes caused by the different positions assumed by the individual or produced by the states (physiologic or pathologic) of the neighboring viscera (stomach, liver). The varying thickness of the superficial tissues and the sexual peculiarities of the chest and mammary configuration must also be taken into account.

Notwithstanding all these difficulties with which we must contend, our post-mortem results do admit of the most practical application, and, when the necessary corrections of age, sex, posture, etc., are made, become of such reliability as to deserve our confidence.

Of the methods heretofore employed for determining the surface positions of the heart and lungs, I will speak briefly of two, namely, transfixion and frozen sections.

Transfixion by long pins is a method subject to many sources of error, and in the end becomes a good deal like guesswork; for, unless the differences between the positions of the pins and the actual position of the viscera under consideration are correctly taken and referred to corresponding points upon the chest, the results from this method will be too uncertain to be depended upon. Frozen sections, carefully made as directed by Prof. Thomas Dwight, will give correct results, but the method is very laborious, takes a great deal of time, can be used only at a certain season of the year, and then only in favorably situated places.

In the face of these difficulties, and with the confusion of mind following a hasty comparison of the measurements given in some of the standard text-books, I cast about for some way of determining these relations for myself, rapidly, accurately, easily, and without reference to place or season, and thought of my camera as a faithful agent to fulfill these diverse requirements.

Composite photography has been applied to the solution of other problems, but I think I am the first to apply it to the determining of the external relations of the heart and lungs. I began my experiments in May, 1893, and would say in this connection that I have applied the same method to solving the abdominal relations with most satisfactory results, which I hope to be able to present to the society at some future occasion.

Before entering upon a description of composite chest photography, I wish to digress for a moment to offer a few comments upon the text-book literature of the subject and to make a plea for greater exactness in such works.

I do not contend that the statements of the various authors must agree with one another—that is impossible from the very nature of the subject—but I wish to object to the sweeping general statement that on close study furnishes us with so very little reliable information. As an example of this style, I quote the following verbatim from a text-book of anatomy: "The heart lies upon the tendinous center of the diaphragm, its base pointing upward and backward, and its apex pointing at the junction of the fifth rib and cartilage." And this is all there is in the entire volume respecting the location of such an important organ as the heart.

Again, I wish to call attention to rules apparently so exact, but really hiding many perplexities, and for the first illustration I shall quote, with all respect, from that storehouse of anatomical information, Quain's Anatomy, Vol. II, ninth American edition, page 493, the following: Speaking of the left border of the heart, and where to draw its outline upon the chest, he says it is indicated by a "line from the third cartilage," etc. Now, the third cartilage is anywhere from  $1\frac{1}{2}$  to  $2\frac{1}{2}$  inches long, about three-fourths of an inch wide. How can such an area be the starting point of a line? One more: Quain and Gray both give the base of the heart as a "line drawn across the sternum on a level with the second costal cartilages." Might we not with propriety ask, Is the upper border or the center or the lower border of these cartilages meant?

Many errors in our text-books are excusable, but I offer that in text-books primarily intended for students, and designed to be as concise and accurate in statement as is consistent with brevity, serious omissions should not be covered by a few generalities, nor should "points" mean any dimension of length up to an inch or any dimension of surface from its proper definition up to an area of 1 or 2 square inches. Again, we meet with difficulties in the application of these statements, however accurate, to the individual. For while in a thin person it is easy enough to recognize cartilages and ribs, when these landmarks are covered with even a moderate layer of fat their recognition becomes uncertain, to say nothing of locating the costo-chondral and chondro-sternal articulations. If I might offer a plan to assist in fixing the relations of the thoracic viscera to the exterior of the chest in connection with the usual landmarks of sternum, ribs, cartilages, and their articulations, I would suggest that we start from the supra-sternal notch and mark the distance to below the ensiform along the median line in inches or centimeters, and the distance of points transversely to the right or left of this line to be given with the distance on the mid-sternal line (from the supra-sternal notch) from which the lateral lines are drawn.

For example, the apex point in Subject I is  $2\frac{1}{4}$  inches transversely to the left of the mid-sternal line (which will be referred to by the letters M. S. L.) at its 7-inch point, i. e., at the point 7 inches from the supra-sternal notch. No matter how thick the layer of adipose tissue is over the chest, and how obscure the cartilages and ribs in consequence become, the supra-sternal notch can always be accurately

determined by the same manœuvre—only reversed—by which the anterior superior iliac spine is fixed; namely, by carrying the thumb from above downward into the notch until it comes in firm contact with the upper margin of the sternum, and from this point make the downward measurement. The measurements to right or left must always be made at right angles to the mid-sternal line.

*Source of error.*—Of course, all chest walls and their contained viscera do not have the same dimensions, and it would be obviously incorrect to apply the results obtained from a large subject directly to a small one. Yet, after the measurements for the average male and female adult are obtained, these can be applied to the determining of similar points in the average person, and the extremes of our scale in the one case to the extremes in the other. Perhaps we can subsequently determine a certain ratio between the chest measurements and its circumference or some other representative measurement that will help us to overcome the above source of error, but my experiments have not yet been sufficiently numerous to justify the formulation of any reliable suggestion in this connection.

*Directions for taking the composite chest photographs.*

Place the subject perfectly horizontal and inject carefully through the carotid (right or left) a thin plaster mixture (colored if desired) to moderate fullness. Some subjects should be used without the injection, but the injection when moderately given, and after it has firmly set, serves to maintain the heart in a fixed position, and is consequently an advantage. Moreover, by distending the heart moderately, as is usually the case, its natural position in diastole will be closely approximated (Subject I) and in those instances where the injection does not fill the ventricles and they happen to remain firmly contracted, you will secure the heart in a state closely allied to its condition during systole (Subject II). Locate the position of the nipples with reference to the ribs and mid-sternal line as previously described, then carefully incise them through their center to the deep parts and mark such places with an aniline pencil so they may be found later on. Remove all superficial tissue and muscles (pectorals and abdominal) over an area sufficiently large to expose the entire chest from above the clavicles to below the lower ribs and from side to side as far as the anterior axillary lines. Expose the trachea, cut it in two below the thyroid cartilage, insert a rubber tube into it, and connect with the bellows or pump. Thoroughly clean the ribs, cartilages, sternum, external intercostal muscles, clavicles, and the origin of the sterno-cleido mastoids. Now place a narrow tape measure or a strip of white paper, upon which the inches have been marked, from the upper margin of the sternum (suprasternal notch) along the middle line to below the ensiform appendix. Upon each cartilage and rib indicate the distance in inches, measured transversely from the mid-sternal line, by narrow strips of white paper as long as the cartilage or rib is wide and placed vertically upon the same to the number of 4 or 5 on either side of the middle line. These strips of paper will help very much in determining the position and direction of the various ribs and cartilages. Set up the camera vertically over the subject, focus on the nipple points (indicated by small circles of white paper), and fix the focus with the set screw. You will need two double plate holders A and B, and very slow plates, numbering the slides A 1 and 2, B 1 and 2. Take the chest in expiration on plates A 1 and 2. (Expiration, first exposure.) The time of this exposure must bear the ratio to the full exposure of about 1 to 3. Inflate the lungs to moderate distention, counting the number of bellows' or pump fulls, and expose plates B 1 and 2. (Inspiration, first exposure.) Let the air escape from the lungs. Remove the sternum from the lower level of the first cartilage to the upper border of the seventh, the included cartilages and ribs for a distance of 4 or 5 inches from the median line. Do not open the pleura. Now inflate the lungs with the same number of bellows' or pump fulls as before.

SUBJECT I.

No. 1.—COMPOSITE PHOTOGRAPH OF CHEST AND HEART; HEART EXPANDED.

Pericardium removed.

SUBJECT I.

No. 3.—COMPOSITE PHOTOGRAPH OF CHEST AND LUNGS IN INSPIRATION.

Pleuræ unopened.

*Expose B 1* (inspiration, second exposure; pleura not opened).—Open the pleural sacs and remove the anterior portions.

*Expose B 2* (inspiration, second exposure; pleura removed).—Allow the air to escape from the lungs.

*Expose A 1* (expiration, second exposure; pericardium intact).—Remove the presenting portion of the pericardium from heart and great vessels.

*Expose A 2* (expiration, second exposure; pericardium removed).

These photographs will give you the position of the lungs, with and without their pleuræ, and of the heart, with and without its pericardium, upon the chest wall from which the necessary measurements can be accurately determined.

By the preceding method the following relations were obtained:\*

*Subject I.*—Adult male negro, apparently about 35 years of age; cause of death unknown. Subject had been injected with chloride of zinc and starch color mixture originally for another purpose, but was used for this experiment.

(A) Nipples: Located over the lower half of the fourth rib,  $3\frac{1}{2}$  inches transversely from the mid-sternal line (and at a point on that line 5 inches from the suprasternal notch) both alike.

(B) Heart: This organ had been distended by the injection, and approximately represented the heart in diastole. Its relations were as follows:

(1) Base: This is taken as the upper limit of the heart. It is indicated by a line drawn across the sternum from just below the middle of the second intercostal space on the right side,  $1\frac{1}{4}$  inches from the mid-sternal line (at its 3 I. P.) to the left to cross the median line (at the  $2\frac{3}{4}$  I. P.) and end at the upper portion of the second left space,  $1\frac{1}{2}$  inches from the mid-sternal line (opposite its  $2\frac{5}{8}$  I. P.).

(2) Apex: Behind the center of the fifth interspace  $2\frac{1}{4}$  inches to the left of the median line (at its 7 I. P.).

(3) Left border: From the left extremity of the base line downward and slightly outward to cross the third costal cartilage 2 inches from the M. S. L. (at its  $3\frac{5}{8}$  I. P.). It continues downward and outward until the fourth interspace is reached, then turns inward as it passes to the apex point. This line crosses the fourth left costochondral articulation, which is  $2\frac{3}{4}$  inches from the M. S. L. (opposite its 5 I. P.), the fourth interspace at the center of which it is  $2\frac{7}{8}$  inches from the M. S. L. (at its 6 I. P.); from here it curves downward and inward, crosses the fifth cartilage  $2\frac{1}{4}$  inches from M. S. L. (opposite the  $6\frac{5}{8}$  I. P.), and ends at the apex (*see* 2).

(4) Right border: Begins at the right end of the base line passes outward and downward across the third right costal cartilage  $1\frac{1}{2}$  inches from the M. S. L. (at  $3\frac{1}{2}$  I. P.) over the third interspace and fourth costal cartilage  $1\frac{3}{4}$  inches from the M. S. L. (the former opposite the  $4\frac{3}{8}$  and the latter the 5 inch points, respectively). It now curves downward and inward, and terminates over the center of the fifth costal cartilage  $1\frac{3}{8}$  inches from the median line (at 6 I. P.).

(5) Lower border: This joins the lower ends of the right and left borders. In doing so it describes a wavy course, with a concavity at each end looking upward, and one in the center, as it crosses the middle line, looking downward. It crosses the sixth and seventh right costal cartilages transversely to their long axes, the median line at its  $6\frac{3}{4}$  I. P., over the middle of the ensiform, and the seventh left costal cartilage very obliquely to reach its lowest point at the lower margin of the sixth costal cartilage,  $1\frac{1}{4}$  inches to the left of the M. S. L. (at  $7\frac{1}{2}$  I. P.), then turns abruptly upward to join the lower extremity of the left border at the apex.

(C) Auricles.

(1) Right: Its upper and outer (right) borders are formed by the portions of the base and right border lines of the heart cut off by a line which forms the inner (left) border of the auricle, and which starts from the base line one-fourth of an inch to the right of the median line and passes directly downward until opposite the lower border of the third right costal cartilage (at the  $3\frac{5}{8}$  I. P. on the M. S. L.); from this point it curves slightly downward, passing outward about parallel with the lower margin of the third costal cartilage, until 1 inch from the M. S. L. (opposite the 4 I. P.), when it turns more abruptly downward and intersects the right border of the heart at the upper margin of the fourth costal cartilage.

(2) Left: This shows us only a very small half-moon shaped space bounded above and on the outside by small adjacent portions of the base and left border of the

\* When a border of the heart or lungs is said to cross a cartilage or intercostal space at a certain distance from the median line the measurement is always made from the center of the cartilage or space unless otherwise stated. The mid-sternal line will be referred to by its initials M. S. L., and the numeral following it in parenthesis, as "at 6 I. P." means at the 6-inch point on the mid-sternal line, measured from the suprasternal notch as already described.

heart. Its inner margin is indicated by a line drawn from a point on the base line 1 inch from the left of the M. S. L. and curving downward to intersect the left border, where it crosses the center of the third cartilage.

(D) Auriculo-ventricular groove: The two extremities of the line indicating this groove correspond to the lower halves of the inner borders of the auricles. The central portion to a line connecting the middle points of these borders and curving slightly upward as it crosses the sternum. This middle portion indicated the line of junction of pulmonary artery and right ventricle.

(E) Coronary arteries.

(1) Right: Runs from the middle point of the inner boundary of the right auricle 1 inch from the median line downward in a nearly straight course to the lower border of the heart three-fourths of an inch from the M. S. L.

(2) Left: This begins similarly at the midpoint of the inner margin of the left auricle and descends almost vertically and about  $1\frac{1}{4}$  inches from the mid-sternal line to the lower border of the heart.

(F) Long axis of the heart: Reaches from the right end of the base line to the apex. It crosses the mid-sternal line (at its  $4\frac{1}{2}$  I. P.) opposite the centers of the sternal ends of the fourth cartilages.

(G) Area of cardiac dullness during inspiration: It is a quadrilateral space, bounded on the right by the median line; below by the lower border of the heart; above by a line drawn from a point on the mid-sternal line ( $4\frac{1}{2}$  I. P.) opposite the centers of the sternal ends of the fourth cartilages along the upper margin of the fifth left cartilage  $1\frac{1}{4}$  inches from the M. S. L. (opposite its  $5\frac{3}{4}$  I. P.); and on the left by a line from the last point downward and inward to cross the lower border of the heart three-fourths of an inch to the left of the median line. Roughly stated this area is an inch and a quarter wide to the left of the median line, limited above by the upper margin of the fifth left cartilage, and below by the lower border of the heart.

(H) Aorta: Its axis corresponds to the median line as far as it is shown in the photograph. Its right border being one-half inch to the right and its left the same distance to the left of the median line, the former reaching from the base (one-half inch to the right of the M. S. L.), and the latter appearing above the pulmonary artery and both disappearing under the upper sternal fragment.

(I) Pulmonary artery: This occupies the intervening space between the auricles and is limited below by the line for the auriculo-ventricular groove. It is about  $1\frac{1}{4}$  inches wide at its base and extends above the base line about one-half inch where it disappears under the aorta. It conceals the origin of the left portion of the aorta.

(J) Superior vena cava: This shows as nearly vertical and three-fourths of an inch wide along the right side of the aorta. Its right border begins from the point of intersection of the right heart border and the upper margin of the third costal cartilage, and passes directly upward to disappear under the upper sternal fragment. Its left border is indicated by the same line as the right margin of the aorta.

(K) Lungs: In inspiration (moderately inflated) and contained within the unopened pleuræ. Their anterior edges alone traced.

(1) Right: The anterior border of the right lung is nearly vertical for a considerable part of its extent. It appears (in the photograph) issuing from beneath the upper fragment of the sternum opposite the  $1\frac{1}{2}$  I. P. of the M. S. L., and distant from it one-half inch to the right. It passes downward and inward to cross the mid-sternal line at its  $1\frac{3}{4}$  I. P. (opposite the first interspace) and reaches one-fourth inch beyond the center line toward the left. From here it descends vertically parallel with and one-fourth inch from the middle line until on a level with the center of the sternal ends of the fifth cartilages (opposite the 5 I. P. on the M. S. L.), where it turns to the right, crosses the median line, and passes downward and outward, following the direction of the upper margin of the sixth cartilage.

(2) Left: Its outline is more irregular than the right, as it has a large notch for the accommodation of the heart. Like the right, it comes out from the upper portion of the sternum the same distance to the left of the middle line at the same point ( $1\frac{1}{2}$  I. P.), passes downward toward the right and meets the right lung on a level with the upper border of the second costal cartilages (opposite the 2 I. P. on the M. S. L.). From here the inner borders of the two lungs (separated only by the pleuræ) remain in close contact until opposite the middle point between the fourth cartilages ( $4\frac{1}{2}$  I. P. on M. S. L.), when the left lung abruptly leaves the other and passes outward and downward parallel with the upper border of the fifth costal cartilage until  $1\frac{1}{4}$  inches from the M. S. L. (opposite its  $5\frac{3}{4}$  I. P.); it now passes downward and slightly inward until the sixth cartilage is reached, which it follows outward to the left along its upper margin.

(3) This notch in the left lung exposes the lower portion of the heart and forms the upper and outer boundary of the area of the heart exposed in inspiration. The inner border of this space agrees with the median line and its lower with the lower margin of the heart.

SUBJECT II.

No. 2.—COMPOSITE PHOTOGRAPH OF CHEST AND HEART; HEART CONTRACTED.

Pericardium removed.

SUBJECT II.

No. 4.—COMPOSITE PHOTOGRAPH OF CHEST AND LUNGS IN INSPIRATION.

Pleuræ unopened.

*Subject II.*—Adult male; white; about 45 years of age; cause of death unknown. Subject had been injected with zinc chloride and plaster color mixture.

(A) Nipples: These are situated  $3\frac{1}{2}$  inches from the median line on the extreme lower margin of the fourth rib. As the left ribs slope down slightly farther than the right, it follows that when referred to the median line the left nipple is one-fourth inch lower than the right (or the left is opposite the  $5\frac{1}{4}$  I. P. and the right opposite the 5 I. P. on the M. S. L.).

(B) Heart: The auricles and aorta were injected, but the ventricles were not and were in a state of firm contraction, and so represent fairly accurately the position of the heart in systole.

(1) Base: This is indicated by a line from just above the upper margin of the third right costal cartilage,  $1\frac{5}{8}$  inches from the M. S. L. (at its  $3\frac{1}{2}$  I. P.), drawn across the sternum to end three-fourths of an inch to the left of the median line opposite the center of the second interspace (at the  $3\frac{1}{4}$  I. P. on M. S. L.).

(2) Apex: Over the center of the seventh left costal cartilage, three-fourths of an inch from the median line (opposite its  $7\frac{1}{2}$  I. P.).

(3) Left border: From the left extremity of the base line nearly vertically downward to the apex point; it crosses the cartilages of the third, fourth, fifth, and sixth ribs at a distance of seven-eighths of an inch from the M. S. L. (opposite the following points on this line: Third,  $3\frac{7}{8}$  I. P.; fourth, 5 I. P.; fifth, 6 I. P.; sixth, 7 I. P.).

(4) Right border: From the right extremity of the base line downward and slightly outward to the middle of the fourth costal cartilage,  $1\frac{3}{4}$  inches to the right of the M. S. L. (at its 5 I. P.). In crossing the third cartilage, it is  $1\frac{5}{8}$  inches from the same line (at its  $3\frac{7}{8}$  I. P.). The line now passes downward and inward to the center of the fifth cartilage, 1 inch from the M. S. L. (opposite the 6 I. P.).

(5) Lower border: Really continues the direction of the right border from the last point above, downward and inward in a nearly straight direction to cross the median line at its  $7\frac{1}{2}$  I. P. over the xipho-sternal articulation. To the left of the median line it descends a slight distance as it passes outward until about three-fourths of an inch from the same, when it turns upward to the apex and joins the lower extremity of the left border. This line is slightly concave downward and toward the right as it crosses the sixth and seventh right cartilages.

(C) Auricles.

(1) Right: Presents a pear-shaped outline in the photograph, its upper and outer margins being formed by the adjoining parts of the base and right border of the heart. Its inner boundary is indicated by a line from the base one-half inch to the right of the median line, passes vertically downward for three-fourths of an inch, then downward and outward to intersect the right border where it crosses the upper margin of the fourth costal cartilage.

(2) Left: Shows as the merest oval space in the angle of the base line and left border, and limited on the inside by a line drawn downward and outward from a point on the base one-half inch to the left of the median line to the left border at the lower margin of the third costal cartilage.

(D) Auriculo-ventricular groove: This is indicated at either extremity by the lower portions of the inner auricular margins, and its central portion by joining these two extremities by a line slightly convex upward as it crosses the M. S. L. (at its 4 I. P.) opposite the lower margins of the third costal cartilages.

(E) Coronary arteries.

(1) Right: This comes out from under the lower and middle thirds of the inner border of the right auricle nearly 1 inch to the right of the median line, and with many turns and twists, due to the contracted state of the heart, passes downward nearly vertically to the lower border of the heart.

(2) Left: This shows on the extreme left of the heart, issuing from the lower portion of the inner margin of the left auricle and descending directly to the apex, varying in its distance from the left of the median line from three-fourths of an inch in the upper third to one-half of an inch in the lower third of its course.

(F) Long axes of the heart: From a point on the base  $1\frac{1}{4}$  inches to the right of the median line to the apex. This crosses the middle of the sternum (opposite the 6 I. P.) on a level with the lower border of the fifth cartilages.

(G) Area of heart exposed in inspiration: Owing to the contracted state of the heart its entire lower portion to the left of the mid-sternal line and below the lower border of the fourth left cartilage is uncovered.

(H) Aorta: Right border. This is shown by a line from the right extremity of the base drawn vertically upward across the second costal cartilage  $1\frac{3}{4}$  inches from the M. S. L. (at its  $2\frac{3}{4}$  I. P.) then curved upward and toward the left to pass under the upper sternal fragment  $1\frac{1}{2}$  inches from the M. S. L. (at the 2 I. P.). The left border is covered at its beginning by the pulmonary artery and only shows as a short curved line reaching from the level of the lower margin of the second right costal cartilage one-fourth inch from the median line (at 3 I. P.) toward the left to cross the M. S. L. on a level with the upper margin of the second costal cartilages (at the  $2\frac{1}{4}$  I. P.).

(I) Pulmonary artery: Occupies the interauricular space; with this width it passes upward, curving toward the left, and disappears on a level with the upper border of the second cartilages.

(J) Superior vena cava: Does not appear in the photograph.

(K) Lungs: In inspiration (moderately inflated) inclosed within the unopened pleural sacs.

(1) Right: Appears from under the upper fragment of the sternum 1 inch to the right of the M. S. L. (at its  $1\frac{1}{2}$  I. P.), passes downward and inward, crosses the middle line (at its  $2\frac{1}{2}$  I. P.) opposite the upper border of the second cartilages, continues its course to about one-fourth inch to the left of the median line, and then descends nearly parallel with the same, and at an average distance from it of one-fourth inch until opposite the upper margin of the sixth costal cartilages (at the  $6\frac{1}{2}$  I. P. on the M. S. L.) it bends to the right, crosses the mid-sternal line (at its  $6\frac{3}{4}$  I. P.), and runs outward and downward parallel with the upper margin of the seventh costal cartilage.

(2) Left: This issues 1 inch to the left of the median line opposite the same point ( $1\frac{1}{2}$  inch) as the right, inclines downward and inward until at the lower margin of the second costal cartilage (left) it takes a course parallel with and nearly half an inch from the (left of the) median line until just below the lower border of the fourth left cartilage (at the  $5\frac{3}{8}$  I. P. in M. S. L.), where it turns transversely outward for one-half inch, then downward and outward to the fifth intercostal space an inch from the M. S. L. (at its  $6\frac{3}{4}$  I. P.). It now bends inward to meet the upper margin of the seventh costal cartilage, then turns outward along the upper margin of the same. The two lungs come in contact for only one-fourth of an inch opposite the lower margin of the third cartilage.

(3) The amount of heart uncovered by the left lung is in this case an area at the left of the median line an inch wide and nearly 2 inches long, reaching from the lower border of the fourth to that of the sixth left cartilage.

*Subject III.*—Adult female; white; about 25 years old; well formed and quite muscular; probable cause of death pneumonia (double). Subject was not injected. A different plan was followed in this instance from that in the two preceding cases. The subject was firmly strapped to a tilting table and suspended by the neck in a nearly vertical position. The camera was adjusted, focused, and set. Then negatives of the chest (before and after dissection), of the heart (with and without the pericardium), and of the lungs were made without disturbing the subject or camera, and these negatives fit upon each other perfectly, so that after prints were made the measurements were obtained by placing the photograph of the heart or lungs over that of the exterior of the thorax and tracing upon the latter the outlines of the former by pricking through the two with a pin. This method gives good results provided no change of focus or of the position of subject or camera is made. As the images of the deeper structures are not obscured by those of the more superficial ones, perfect outlines of the heart, with its vessels, and of the lungs can be obtained by tracing them as above shown.

(A) Nipples: The breasts were small (for a female of this size) and firm.

(1) Right: In the center of the fourth interspace 4 inches from the M. S. L. (opposite its  $5\frac{1}{4}$  I. P.).

(2) Left: Over the lower margin of the fourth rib, 4 inches from the mid-sternal line (at same point as above).

The ribs on the left side curve downward slightly more than on the right, and this accounts for the different relations of the two nipples with reference to the thoracic wall. Referred to the median line they are exactly on the same level.

(B) Heart: This organ, with its vessels, was only moderately distended with blood.

(1) Base: Begins in the center of the third interspace,  $1\frac{1}{8}$  inches to the right of M. S. L. (at its 4 I. P.), curves slightly upward as it passes to the left to cross the median line (at its  $3\frac{1}{2}$  I. P.), on a level with the lower border of the third costal cartilages, and ends  $1\frac{1}{2}$  inches to the left of the M. S. L. (at its  $3\frac{1}{4}$  I. P.) at the upper margin of the third costal cartilage.

(2) Apex: The apex point is over the interchondral articulation of the cartilages of the fifth and sixth left ribs  $1\frac{1}{2}$  inches from the M. S. L. (at its  $7\frac{1}{2}$  I. P.).

(3) Left border: Begins at the left extremity of the base line, passes downward, inclining slightly outward until the middle of the fourth interspace is reached, 2 inches from the M. S. L. (at its  $6\frac{1}{4}$  I. P.). From here it turns downward and toward the right to end at the apex point. The left border crosses the third costal cartilage  $1\frac{1}{2}$  inches from the M. S. L. (at  $3\frac{3}{4}$  I. P.), the fourth cartilage 2 inches from the same (at the  $5\frac{1}{2}$ -inch point), and the fifth cartilage  $1\frac{3}{4}$  inches (at the  $6\frac{7}{8}$  I. P.).

(4) Right border: Extends from the right extremity of the base line vertically downward to the center of the sixth costal cartilage 1 inch from the M. S. L. (at its  $6\frac{1}{4}$  I. P.). This border crosses the fourth and fifth cartilages at the same distance from the median line (the former opposite the  $4\frac{1}{2}$  and the latter the  $5\frac{1}{2}$  I. P.).

(5) Lower border: Is indicated by a line from the lower end of the right border drawn downward and toward the left to cross the seventh right cartilage transversely to its long axis, the mid-sternal line (at its  $7\frac{1}{4}$  I. P.), over the middle of the ensiform, continues still downward and toward the left to the center of the sixth left costal cartilage 1 inch from the M. S. L. (at its  $7\frac{1}{2}$  I. P.), then curves upward to end at the apex point and connect with the lower end of the left border. This line is slightly concaved upward and to the left as it crosses the median line.

(C) Auricles.

(1) Right: The inner border is indicated by a line which starts from the base one-fourth of an inch to the left of the M. S. L., passes vertically downward until opposite the middle of the sternal ends of the fourth cartilages (at  $4\frac{1}{2}$  I. P. of the M. S. L.), where it turns toward the right across the median line (at its  $4\frac{3}{8}$  I. P.), then with a slight convexity toward the right shoulder passes to meet the right border of the heart as it crosses the lower margin of the fifth costal cartilage.

The auricle is bounded on its upper and outer sides by the adjoining portions of the base and right border of the heart. In this case the auricle reaches to the left one-fourth of an inch beyond the median line.

(2). Left: This is a very small space cut off at the angle of junction of the base and left border by a line beginning seven-eighths of an inch to the left of the M. S. L. on the base line and passing downward and outward to meet the left border at the lower margin of the third costal cartilage.

(D) Auriculo-ventricular groove: Corresponds to a line joining the middle points of the inner auricular boundaries plus the lower halves of these borders.

(E) Coronary arteries.

(4) Right: Issues from the inner border of the right auricle one-half inch to the right of the M. S. L. and passes downward and inward to the lower margin of the heart at the median line.

(2) Left: This issues from the inner border of the left auricle,  $1\frac{1}{4}$  inches from the mid-sternal line, and passes vertically downward until near the apex, when it turns inward to reach the lower border one-half inch to the left of the median line.

(F) Long axis of the heart: From the base line three-fourths of an inch to the right of the M. S. L. to the apex point. It crosses the median line (at its  $4\frac{3}{4}$  I. P.) opposite the upper border of the fifth cartilages.

(G) Area of heart exposed in inspiration was not determined, owing to the condition of the lungs in expiration—the lungs collapsed. The entire lower two-thirds of the heart to the left of the median line and below the level of the upper margin of the fourth costal cartilage is exposed.

(H) Aorta: In width as shown in the photograph about 1 inch. Its right border starts from the base 1 inch to the right of the M. S. L. and passes upward across the third cartilage seven-eighths of an inch from the median line (at the  $3\frac{1}{2}$  I. P.) across the second cartilage five-eighths of an inch from the central line (at the 2 I. P.), and is lost curving toward the left under the upper sternal fragment. Its left border shows only for a short distance curving over the pulmonary artery from right to left about 1 inch from and parallel with the right border.

(I) Pulmonary artery: Includes the space left between the auricles and also comes from behind the entire inner half of the left auricle. It reaches as high as the lower margin of the second costal cartilage (opposite the  $2\frac{1}{4}$  I. P. on the M. S. L.).

(J) Superior vena cava: Shows in a collapsed state to the right of the aorta. Its right border reaches from the extreme right end of the base vertically upward to disappear under the upper sternal fragment and cartilage of the first rib. Its left margin is the same as the right for the aorta (in the photograph).

(K) Lungs: These could not be inflated satisfactorily (death due to a double pneumonia), so no attempt at securing photographs of them in inspiration was made.

The following measurements give the outlines of the anterior margins of the lungs in their partially collapsed state, pleuræ removed:

(1) Right: The anterior border appears above in the median line (at the  $1\frac{1}{2}$  I. P.), passes downward and to the left of M. S. L. until opposite the center of the second interspace (at the  $2\frac{1}{2}$  I. P. on the M. S. L. and one-fourth of an inch to its left), runs parallel with the median line until (opposite its  $3\frac{3}{4}$  I. P.) on a level with the center of the third space, when it curves downward and toward the right and is lost running parallel with the upper margin of the sixth costal cartilage.

(2) Left: Issues from the upper sternal fragment three-eighths of an inch to the left of the M. S. L. (at the same  $1\frac{1}{2}$  I. P. as above), descends, almost touching the right lung, until opposite (the  $3\frac{1}{2}$  I. P. on the M. S. L.) the lower border of the third cartilage it turns outward toward the left along the upper margin of the fourth costal cartilage until it reaches the left border of the heart, which it follows until near the apex, then turns to the left, following the curve of the sixth costal cartilage (upper margin).

(3) Area of heart exposed in expiration (*see* § G preceding).

*Comparative measurements.*

- (1) Base of heart:
  - a. "Level of second costal cartilages." Quain, Gray.
  - b. "Below level of second costal cartilages." McLachlan, Allen, Sibson.
  - c. "Second right interspace to left first interspace." Wilson.
  - d. Just below middle of right to above middle of left second interspaces.  
Haynes, Subject I.
  - e. "Upper border of third costal cartilages." Holden, Treves.
  - f. "Junction of third cartilage with right border of sternum." McClellan.
  - g. "Upper margin of third right cartilage to center of second left space."  
Haynes, Subject II.
  - h. "From center of third right space to upper margin third left cartilage."  
Haynes, Subject III (suspended vertically).
- (2) Length of base:
  - a. Not given. Quain, Gray, McClellan.
  - b. "One-half inch to right and 1 inch to left of sternum." Holden.
  - c. "One-half inch to right and  $1\frac{1}{2}$  inches to left of sternum." McLachlan.
  - d. "One inch to right and  $2\frac{1}{2}$  inches to left of sternum." Wilson.
  - e. Haynes—  
Subject I,  $1\frac{1}{4}$  inches to right and  $1\frac{1}{2}$  inches to left of median line =  $2\frac{3}{4}$  inches.  
Subject II,  $1\frac{5}{8}$  inches and  $\frac{3}{4}$  inch, respectively, =  $2\frac{3}{8}$  inches.  
Subject III,  $1\frac{1}{8}$  inches and  $1\frac{3}{8}$  inches, respectively, =  $2\frac{1}{2}$  inches.
- (3) Apex point:
  - a. "In fifth left interspace  $3\frac{1}{2}$  inches from median line." Quain, Gray, McLachlan, McClellan.
  - b. With reference to left nipple, " $1\frac{1}{2}$  inches below and three-fourths inch to inside," Quain, Gray; "2 inches below and 1 inch to inside, Holden;" "2 inches below and one-half inch to inside," Wilson.
  - c. "Fifth left interspace at costo-chondral articulation," Treves.
  - d. Haynes:  
Subject I. Fifth left space  $2\frac{1}{4}$  inches from M. S. L. (at its 7 I. P.).  
Subject II. Behind center seventh left cartilage three-fourths inch from M. S. L. (at its 7 I. P.). Heart in I distended, in II contracted.  
Subject III. Behind interchondral articulation between fifth and sixth cartilages  $1\frac{1}{2}$  inches from M. S. L. (at its  $7\frac{1}{2}$  I. P.). Subject suspended, heart moderately distended with blood.
- (4) Right border: The farthest point reached from the mid-sternal line. Quain says  $1\frac{1}{2}$  inches. None of the other writers I consulted mentioned it.  
Haynes—Subject I,  $1\frac{3}{4}$  inches over fourth cartilage; subject II,  $1\frac{3}{4}$  inches over fourth cartilage; subject III, 1 inch over fourth cartilage.
- (5) Left border: Farthest point reached from the mid-sternal line. None of the above writers referred to it.  
Haynes—  
Subject I. Heart distended "in diastole,"  $2\frac{7}{8}$  inches over the center of the fourth interspace.  
Subject II. Heart contracted "in systole," seven-eighths inch over center of fifth cartilage.  
Subject III. Midway between "systole" and "diastole," 2 inches over fourth interspace.
- (6) Lower border: The point at which it crosses the sternum.
  - a. "Bottom of sternum," Holden.
  - b. "Xipho-sternal articulation," McLachlan.
  - c. "Upper third of ensiform," Quain.
  - d. Haynes—  
Subject I. Middle of ensiform.  
Subject II. Xipho-sternal articulation.  
Subject III. Middle of ensiform.
- (7) Area of cardiac dullness in inspiration.
  - a. Quain: "Two lines from point of apex beat to the middle line of the sternum; one horizontal, the other obliquely upward to between the fourth cartilages.
  - b. Gray quotes from Holden.
  - c. Holden quotes from Latham: "Make a circle 2 inches in diameter round a point midway between the nipple and end of the sternum."
  - d. Treves quotes from Latham.
  - e. McClellan: "Line from middle of the sternum opposite fourth left costal cartilage to the point of junction of the left fifth rib and its cartilage, and from this point horizontally back to sternum."

## (7) Area of cardiac dullness in inspiration—Continued.

f. Haynes—

Subject I. A quadrilateral space bounded on right by median line, below by lower border of heart; above by a line from middle of fourth cartilages along upper margin of fifth left cartilage to  $1\frac{1}{2}$  inches from median line; on left by a line from last point downward to intersect the lower border of the heart three-fourths of an inch from the left of the median line.

Subject II. Heart contracted. All of the heart to the left of the median line and below the lower margin of the fourth left cartilage.

Subject III. Lungs (in expiration) collapsed. Entire lower two-thirds of heart to left of median line and below the upper margin of the fourth left cartilage.

## (8) Auricles:

a. Quain: "The right auricle lies behind the sternal ends of the third, fourth, and fifth cartilages, and the intervening portions of the intercostal spaces, and is also partially covered by the right edge of the sternum. The point of its auricular appendage is exactly behind the middle line on a level with the upper border of the third costal cartilage. The left auricle extends vertically from the level of the lower border of the second left cartilage to the upper border of the fourth (sternal end). The apex of its appendage is in the lower part of the second intercostal space, or behind the third costal cartilage, about  $1\frac{1}{4}$  inches from the left of the sternum."

b. Haynes—

Subject I. Right: The outline in the photograph is markedly "ear-shaped." It is behind the first inch of the third right costal cartilage with the adjacent border of the sternum and the third space. Left: Oval outline one-half inch by 1 inch placed over a portion of the second space and third cartilage. The center of the area being  $1\frac{1}{4}$  inches from the left of the median line and its long axis extending from above downward and toward the left.

Subject II. Right: Pear-shaped outline, base uppermost covers first inch from sternum of third right cartilage and space. Left: Behind the chondro-sternal articulation of the third left cartilage; oval shaped; long axis as in No. I.

Subject III. Right: Distinctly auricular shaped. Includes fourth and fifth right cartilages for 1 inch from sternum and the included space, with the right half of sternum opposite the fourth chondro-sternal articulation. Left: Behind the third left cartilage, its center  $1\frac{1}{4}$  inches from the median line, its long axis inclined as in No. I, and the shape the same.

## (9). Auriculo-ventricular groove—

a. Quain: "The auriculo-ventricular sulcus corresponds with a line drawn obliquely upward from near the sternal end of the sixth costal cartilage on the right side to the third cartilage on the left."

b. Haynes—

Subject I. (Approximately stated.) A curved line, with the convexity upward from the upper margin of the fourth right cartilage,  $1\frac{3}{4}$  inches from the median line to the middle of the third left cartilage,  $1\frac{3}{4}$  inches from the middle line. This line crosses the center of the sternum on a level with the lower border of the third cartilages.

Subject II. This line takes the same course as in No. I, except it ends at the lower margin of the third left cartilage, seven-eighths of an inch from the median line.

Subject III. (Suspended.) A line convex upward from the upper margin of the sixth right costal cartilage, 1 inch from the median line to the lower border of the third left cartilage,  $1\frac{3}{4}$  inches from the central line. The sternum is crossed on a level with the lower border of the fourth cartilages.

## (10) Aorta (first portion):

a. Commences "behind the sternum, on a level with the lower border of the third costal cartilage on the left side, and rises as high as the upper border of the second costal cartilage of the right side. Its length is about 2 or  $2\frac{1}{4}$  inches." Quain.

b. "Commences on a level with the lower border of the third costal cartilage behind the center of the sternum; passes obliquely upward to the right side as high as the upper border of the second right costal cartilage. It is about 2 inches long." Gray.

c. "Its origin is on the left side of the middle of the sternum, about on a level with the lower border of the third costal cartilage, ascends with a slight curve, the convexity looking forward and to the right side as far as the upper border of the second costal cartilage of the right side. It is about 2 inches in length." Holden.

## (10) Aorta (first portion)—Continued.

*d.* "The aortic opening is behind the left border of the sternum close to the lower edge of the third cartilage. The trunk ascends behind the second cartilage of the right side." Treves.

*e.* Haynes—

Subject I. Its axis corresponds to the median line. It is about an inch wide and reaches from the upper border of the third cartilages to the middle of the cartilage of the first rib. It is about 2 inches long.

Subject II. The aorta reaches from the upper border of the third right cartilage to the upper margin of the first cartilage. It is entirely to the right of the median line for the first two-thirds of its course and only curves toward the left after reaching the upper margin of the second cartilage. Same length as in Subject I.

Subject III. (Suspended, not injected.) Reaches from the upper level of the fourth cartilages at their sternal junction, entirely to the right of the median line upward to the lower level of the first cartilage, where its center is behind the mid-sternal line.

## (11) Pulmonary artery:

*a.* Quain: "The pulmonary orifice is placed opposite the upper margin of the third left costal cartilage, close to the sternum. The artery proceeds upward to its bifurcation behind the second costal cartilage. It is nearly 2 inches long."

*b.* Treves: Essentially same as Quain.

*c.* Gray, Holden: Do not give its surface relations.

*d.* Haynes—

Subject I. Begins on a level with the lower border of the third cartilages; its center being half an inch to the left of the middle line. It proceeds upward and toward the left and terminates just above the lower margin of the second left cartilage; here its center is about three-fourths of an inch to the left of the median line. The artery is a little over an inch wide and  $1\frac{1}{2}$  inches long.

Subject II. Begins on a level with the lower margin of the third cartilages; its center behind the median line proceeds upward, inclining a little to the left, and ends on a level with the upper border of the second cartilages, its center being one-fourth of an inch to the left of the median line. It is about 1 inch wide and  $1\frac{1}{2}$  inches long.

Subject III. Begins on a level with the lower margin of the third left cartilage entirely to the left of the middle line, being about  $1\frac{1}{4}$  inches wide, passes upward until opposite the middle of the second left cartilage, where the center of the vessel is three-fourths of an inch from the left of the median line. It is a little over an inch wide at its beginning and about  $1\frac{1}{2}$  inches long.

## (12) Coronary arteries. Haynes:

Subject I. (Heart distended.) They run nearly vertical and parallel with the median line, the right 1 inch and the left  $1\frac{3}{8}$  inches from the same; the former from the lower border of the third right cartilage, and the latter from the middle of the third left cartilage, and each extends to the lower level of the sixth cartilage.

Subject II. (Heart contracted.) Right artery is at an average distance of seven-eighths of an inch from M. S. L., parallel with same (nearly), and extends from upper border of fourth to upper border of sixth cartilage. Left is parallel with central line and three-fourths of an inch from it, and reaches from lower level of third cartilage to apex.

Subject III. (Heart moderately distended.) Right: From upper border of fifth cartilage close to sternum to middle of ensiform. Left: From lower margin of third cartilage 1 inch to left and parallel with median line toward apex.

## (13) Anterior margin of the lungs and the extent of their contact during inspiration.

*a.* Quain: "Meet at junction of manubrium and body of sternum, descend together, right sometimes projecting a little to left of middle line, as far as the fourth costal cartilage; right lung continues straight course to sixth costo-chondral articulation; left slopes outward behind fifth costal cartilage, indicated by a line from fourth left chondro-sternal articulation to apex point."

*b.* Gray. Holden: "Anterior border of right lung corresponds to median line from junction of first and second pieces of sternum as low as sixth costal cartilage; anterior border of left lung lies in the middle line only as far as the fourth costal cartilage."

(13) Anterior margin of the lungs and the extent of their contact during inspiration—Continued.

c. Treves: "Meet in middle line at junction of manubrium and gladiolus; right continues vertically downward behind middle line to sixth chondro-sternal articulation; left keeps close to right to fourth chondro-sternal articulation, when it turns off, following a line from fourth cartilage to apex of heart."

d. Haynes—

Subject I. Converge from apices and meet at level of upper border of second cartilages one-fourth inch to left of median line and run parallel with same to level of the upper border of fourth cartilages. The right lung continues at the left of the middle line until at the upper margin of the sixth chondro-sternal articulation, when it crosses to the right. The left turns outward along the upper margin of the fifth cartilage. Length of contact, nearly 3 inches.

Subject II. Anterior of right lung crosses to the left of the middle line on a level with the upper border of second cartilages and continues straight down to lower level of sixth costal cartilages at sternum. The left nearly meets the right at lower level of second left costal cartilage, continues nearly in contact (and opposite third space in actual contact) to level of upper border of fifth left cartilage at sternum, along which it passes outward and toward the left.

(14) Points on the mid-sternal line opposite the centers of the sternal ends of the costal cartilages:

| Number of cartilage. | Subject I.<br>(Male.) | Subject II.<br>(Male.) | Subject III.<br>(Female.) |

(15) Relative position of nipples. All the authorities agree in placing them in the fourth interspace, three-fourths of an inch external to the junction of the ribs and cartilages, or rather more than 4 inches from the median line.

In the two male subjects (I and II), the nipples were over the lower half of the fourth ribs, 3½ inches from the median line. In the female (Subject III), they were 4 inches from the median line, the right in the center of the fourth interspace and the left over the lower margin of the fourth rib. In the males the measurements were made upon the thorax after removal of the superficial tissues; in the female upon the exterior of the chest before such dissection.

From a comparison of the preceding quotations and the original measurements we see that at many critical points there is a wide difference between the accepted relations given in the text-books and those revealed by composite photography.

As regards the lungs, these differences are so small as to be of little importance, but in reference to the heart are so pronounced as to make us wonder if the currently stated relations of heart and chest do not need revision. For example, is it not possible, nay, more than probable, that the authorities, in placing the apex beat

3½ inches to the left of the median line, have not gone at least an inch over the mark? For the apex point in Subject I, where the heart is fully distended, is only 2¼ inches from the median line.

Neither can it be said in explanation of this difference that the heart has been moved bodily toward the right. It has not we can see, for its right border only reaches 1¾ inches from the middle line. Nor can it be claimed that the heart has been foreshortened by the camera at the expense of the chest, for the heart in the photograph is nearly 5 inches wide. Besides, this error of foreshortening is prevented by measuring the distances upon the bony framework of the chest itself before taking the photographs, and any foreshortening of the heart is compensated for by the same occurrence in the image of the chest, and the results are unimpaired. Moreover, the heart has not received complete treatment by the authorities quoted, in that its auricles, borders, and its great vessels have not been traced in sufficient detail upon the bony framework of the chest. This is due no doubt to the uncertainties of the methods used for ascertaining these relations. In these composite photographs the relations lost by the former method are brought out with remarkable clearness and can be readily traced, and their details have been given in the preceding pages, too full to produce attractive reading, but not, I hope, for accurate reference.

In concluding this paper I offer the following summary of the external relations of the viscera in question. These results comprehend the conclusions derived from the statements of the authors consulted and from my own observations.

#### CONCLUSIONS.

(1) Base of heart: A line crossing the sternum obliquely from the upper margin of the third right to the lower border of the second left costal cartilage, 1½ inches from the median line on each side.

(2) Apex: In the fifth space, near the upper margin of the sixth costal cartilage, 2½ inches to the left of the median line.

(3) Right border: From the right end of base curved slightly outward to reach a point 1¾ inches from right of middle line over the fourth cartilage and end at the center of the fifth cartilage, 1 inch from the mid-sternal line.

(4) Left border: From the left end of base, with a convexity outward, to the apex. It reaches its greatest distance of 3 inches from the sternal center over the fourth space.

(5) Lower border: A line curved downward at its beginning (at lower extremity of right border) and ending (at the apex), and slightly convex upward in its center as it crosses the middle of the ensiform.

(6) Heart dullness: A quadrilateral area to left of median line and below the upper border of the fifth cartilage, nearly 2 inches in vertical and 1½ in extreme lateral measurements.

(7) Auricles: Right "ear-shaped" (facing to left), covering the first inch of the third right space and cartilage with the portion of the sternum adjacent to the latter. Its long axis measures about 2 inches and is inclined from above downward and outward. Left, is a small oval space ½ by 1 inch (its center 1¼ inches to left of median line) behind the second left space and third cartilage. Its long axis directed from above downward and outward.

(8) Auriculo-ventricular groove: Is indicated by a line from the right to the left heart borders, beginning on a level with the upper margin of the fourth right, and ending on a level with the lower edge of the third left cartilage. This line is convex upward and crosses the middle of the sternum on a level with the lower border of the third cartilage.

(9) Aorta: A little more than an inch wide and 2 inches long. Extends from the upper border of the third to behind the middle of the first cartilages. At its beginning and ending its center is behind the median line, but in the middle of its course the artery is convex toward the right.

(10) Pulmonary artery: About  $1\frac{1}{4}$  inches wide and  $1\frac{1}{2}$  inches long (in the photograph). Begins on a level with the lower border of the third and ends behind the middle of the second left cartilages. Below, its center is one-half inch and above, three-fourths of an inch to the left of the median line.

(11) Coronary arteries: Both are nearly vertical (incline slightly toward the median line at their lower ends). Right, 1 inch from mid-sternal line. Extends from the upper border of fourth to lower of sixth cartilages. Left,  $1\frac{3}{8}$  inches from middle line in expansion and three-fourths inch in contraction. Extends from middle of third to lower border of sixth cartilages.

(12) The anterior margins of the lungs in inspiration: Right, lies to left of median line, one-fourth inch from and parallel with it from the upper margin of second to that of sixth cartilages (sternal ends). The left is in contact with the right from the upper border of the second to the midpoint between the fourth cartilages, where it turns downward and outward along the upper margin of the fifth left cartilage. Length of contact,  $2\frac{1}{2}$  inches.

(13) The centers of the sternal ends of the costal cartilages are opposite the following distances on the mid-sternal line measured from the supra-sternal notch.

| Cartilages. | (a) Male (average of 2).<br>Distances from each other. |                | (b) Female. Distances from each other. |                |
|-------------|--------------------------------------------------------|----------------|----------------------------------------|----------------|
|             |                                                        |                |                                        |                |
| No. 1.....  | $1\frac{5}{8}$                                         | -----          | 1                                      | -----          |
| No. 2.....  | $2\frac{3}{4}$                                         | $\frac{3}{4}$  | 2                                      | 1              |
| No. 3.....  | $3\frac{5}{8}$                                         | $1\frac{1}{4}$ | $3\frac{1}{4}$                         | $1\frac{1}{4}$ |
| No. 4.....  | $4\frac{3}{4}$                                         | $1\frac{1}{8}$ | $4\frac{1}{4}$                         | 1              |
| No. 5.....  | $5\frac{1}{2}$                                         | $\frac{3}{4}$  | 5                                      | $\frac{3}{4}$  |
| No. 6.....  | $6\frac{1}{4}$                                         | $\frac{3}{4}$  | $5\frac{7}{8}$                         | $\frac{7}{8}$  |
| No. 7.....  | $6\frac{3}{4}$                                         | $\frac{1}{2}$  | $6\frac{3}{8}$                         | $\frac{1}{2}$  |

(14) Nipples: Over the lower margin of the fourth ribs, 4 inches from the middle line.

### ADDRESS BY THE PRESIDENT, ISAAC OTT, M. D., OF EASTON, PA.

GENTLEMEN: In opening the physiological section of the Pan-American Congress, I have the great pleasure to extend to the medical representatives from the Americas, North and South, as well as the United States, a most cordial welcome. I hope that all our friends will do us the great honor of being present at our meetings, and that they will enter into the discussion of papers which will be presented. You are invited to take a deep interest in the proceedings, as many subjects of importance to scientific and practical medicine will be considered. As this is our first meeting as Pan-Americans, let us make it one of fruition and value to humanity. It is my pleasant duty to announce to you that during our sessions we shall be honored with representatives from other countries, and it is very agreeable to first mention the name of Prof. Johannes Gad, most worthy representative of the University of

Berlin and the *Centralblatt für Physiologie*. I have next to announce the name of Prof. A. B. MacAllum, of Toronto University, who represents most excellently Canadian physiology. With regard to the subject of to-day, I shall only speak of American physiology as far it relates to the United States. I restrict myself to this plan, as I am not sufficiently acquainted with the literature of either North or South America to treat it with any precision.

Before taking up the subject of physiology in detail, it might be well to note the state of physiology abroad at the beginning of this century, for the influence of French physiologists was great up to 1870, since which time we have been greatly reacted upon by the physiologists of Germany, and, to a certain extent, by the French. As we all know, the immortal Haller died in 1777. In France, at this period, Lavoisier published his experiments upon the respiration of animals, and in 1780, in conjunction with Laplace, his great memoir upon animal heat. About the year 1800, the French physiologists were Petit at Namur, Housset, Le-Gallois, and Bichat. In England, in 1811, Charles Bell published his epoch-making memoir on "A New Anatomy of the Brain," at the age of 26. In Germany, Fiedemann and Bendach were the chief exponents of physiological progress. But at the end of the first quarter of this century the mighty influence of Magendie was felt by the introduction of the experimental method in physiology.

In the study of the physiological papers of the United States I shall only take notice of articles containing some original observations, and waste no time on theoretical lucubrations. "*Hablen cartas y callen barbas.*" Further, I shall not pretend to make this review exhaustive, as neither the time nor the libraries are sufficiently accessible to me, yet I shall try not to miss the main papers.

In 1795 Samuel Latham Mitchill, a professor of chemistry in the College of New York, made the observation\* that pulsations of the heart can be accelerated or retarded by the varied state of the respiration. In the year 1800 I find a thesis presented to the University of Pennsylvania by Dr. John Baptiste Clement Rousseau, of Hispaniola. It was upon the subject of absorption, and, singularly to state, the first third of this century is mainly devoted by our writers to this subject. I can only account for it by the fact that the great external use of mercurial ointment in practice led our professional brethren to theorize upon its action and finally to experimentally determine the truth or falsity of their hypotheses. He held that no absorption could take place from the skin unless the cuticle was destroyed by friction, although the cuticular injury might not be apparent to the eye. He states that it never has been decidedly proved that mercury was received and carried into the system by absorbents, for he found no mercury in the urine, milk, or other fluids of animals to whose surface mercury was freely applied. He is not able to positively say, but he states it seems probable, that mercury is volatilized by friction and is absorbed in fine particles like musk and spirits of turpentine. In his first experiment he swallowed, at 10 A. M., a few drops of spirits of turpentine with sugar, water, and sweet spirits of nitre. He soon found a violet odor in the urine. In his second experiment he exposed some turpentine in an open bowl in a close room at the temperature of 61° F. In half an hour he found his urine with an odor of violets. In his third experiment he breathed through a tube opening outside the room, and closed his nose, then exposed turpentine in the room, but no violet odor was perceived in the renal secretion. In the fourth experiment he immersed his hand and wrist in turpentine and breathed through the tube outside the room with nostrils closed, but no violet odor was perceived. In fifth experiment, still breathing through a tube outside room, nostrils closed, then smeared body with turpentine by means of a sponge, but no odor to urine. In experiments, 6, 7, and 8, found inhalation of fumes of turpentine from a bottle sufficient in half an hour to be perceived in the urine. His conclusions were: (1) Absorption is performed by the lungs; (2) absorption is performed by the lungs alone; (3) no substance can be introduced by the skin when the cuticle is sound and entire.

---

\*On Gaseous Oxide of Azote, New York, 1795, 12 mo., p. 12.

In the same year (1800) a thesis of the University of Pennsylvania was published by Dr. James Agnew, of New Jersey, upon the perspiration.\* In 1805 Dr. Dangerfield repeated Rousseau's experiments. He also put large plasters of mercurial ointment to the calves of the legs, bandaged them fast, and covered the whole with a stocking. He wore these eight days, but no ptyalism ensued. He then restricted his diet, bled himself 20 ounces, and then left the plasters on for seven to eight days, but no salivation ensued. In other experiments he applied less mercurial ointment, but with friction, and in three days ptyalism ensued. In another experiment he applied mercurial ointment to upper surface of each foot and wore oilcloth stockings for ten days, without effect. He concludes that substances are not carried to the circulation from sound or abraded skin, but he does not conclude that there are no absorbents beneath the skin.

In 1806 Dr. Reuben D. Mussey, of Massachusetts, published some experiments on cutaneous absorption.† He states that doubts as to the absorption by the skin were first raised by Mr. Segum, of Paris, and by the experiments of Drs. Rousseau, Dangerfield, and Klapp. Although he alludes to Dr. Klapp's experiments, I cannot find any publication of the same before 1811. Since colored substances, as madder, are absorbed by the intestinal canal unchanged, he started some experiments with it. In his first two experiments he immersed himself in a bath of strong watery infusion of madder. He found his urine tinged red in three to five hours and when treated with  $\text{Fe SO}_4$  gave a purplish brown color. In another experiment he was bled three and five hours after the bath, but the blood serum appeared the same. From these experiments he concluded that madder entered the system by cutaneous absorption, and not by the lungs.

In 1809 Dr. J. Redman Coxe‡ published a paper supporting the doctrine of cuticular absorption, but he made no experiments.

In 1811 Dr. Joseph Klapp§ published a paper upon absorption, criticising Dr. Mussey's experiments. He probably was the first man in the United States to make a vivisection. In a dog the trachea was tied off, when a tube from a bottle of turpentine was introduced into the trachea below the ligature. The dog inhaled the turpentine for two hours, when the tube and ligature were removed from the trachea. The urine collected had a strong violet odor. After quoting Dr. Dangerfield's experiments, he arrives at the conclusion that the mercury is volatilized and inhaled by the lungs. To support this view, he had his servant rub mercurial ointment on the inside of the doctor's leg an hour at a time, twice daily, for six days. Dr. Klapp breathed pure air from out of doors by means of tube through a window. At the end of six days he had not the slightest salivation, but the servant was badly ptyalized, so that the experiment was arrested, although the servant wore gloves during the frictions. In this paper he alludes to Dr. Darwin's theory of a supposed occasional conveyance of fluids from the stomach to bladder by supposed inverted motion of urinary lymphatics. To disprove this, Drs. Klapp and Rogers performed the following experiment: Opened the abdomen of a dog; both ureters were tied off above the bladder; urine passed out of bladder; his penis ligated. Dog was then given gin, madder, and nitre for an hour or two. At the end of eleven hours the bladder was found empty. Drs. Smith and Rousseau,|| in 1811, made some experiments upon cuticular absorption. They found, as Mussey, that madder is absorbed by the skin and colors the urine. They found the same to be true of rhubarb. They also state that no astringents, narcotics, or coloring substances have the slightest effect if the nostrils are stopped.

From 1811 to 1821 there is no record of any physiological papers. In 1821 Drs. Richard Harlan, J. B. Lawrence, and B. N. Coats,\* a committee of the Academy of Medicine of Philadelphia, made a report on the means by which absorption is effected. William and John Hunter thought Hippocrates and Galen in error in stating that absorption took place by the veins. The Hunters proved that it was accomplished by the lymphatics. Magendie, about this period, believed it took place by the veins, which was confirmed by Harlan, Lawrence, and Coats. They showed the error of Hunters' experiments. These gentlemen used forty-three animals. Their conclusions were that the coloring matters were not absorbed by the lacteals in the living body. Prussiate of potash enters by the lacteals and thoracic duct. If you mix *nux vomica* and prussic acid you destroy life by an action upon the nerves. Contrary to the assertion of Magendie, ink will not infiltrate the living body. When it was placed in the intestine, peritoneal, and pleural cavities it was not absorbed. The odors of camphor, mint, and *asafetida* infiltrate through the intestine.

The chemical and odorous substances above mentioned are absorbed from the stomach slower than from the intestine, and from the peritoneal cavity even slower and with more difficulty. They showed that absorption does not come from the arteries exclusively. They bled animals to death, tied their aortæ, and then injected saline fluid into the peritoneal cavity and found that some disappeared. In 1822 Dr. John Hubbard† made some experiments upon absorption. He tried to prove that absorption took place by the lymphatics, and not through the walls of the veins and arteries. He exposed in a number of animals the arteries and veins, and placed lead plates on cards underneath the vessel so that the wall of the vessel could be bathed by the solutions without the solutions touching the wound. He then applied prussic acid and *nux vomica* to the walls of the vessels for twenty to thirty minutes, and they had no effect. Later he placed these drugs in the wound and they were promptly absorbed and produced characteristic effects. He also made control experiments to show that the *nux vomica* and prussic acid were good preparations.

In the same year Dr. Robert Melnor‡ published a paper on the absorption of active medicine into the circulation, and also the effects of nutritive enemata. He first shows the physiological action of gamboge and tartar emetic when injected directly into the jugulars of cats and dogs. He then injected *asafetida* into the veins, and found its odor in the blood for some time. He injected milk into the jugular vein in three instances without producing death, showing that nutritive fluids can be directly thrown into the circulation with impunity. He fed a dog upon garlic in meat; afterwards he killed the animal and found the whole body saturated with the odor. The blood gave off the odor of garlic after the animal had been fed on it for a few days. He fed a dog on indigo and found the color in the lacteals. He fed a dog on rhubarb, killed him in one hour and a half, and found rhubarb in the bile. He injected madder into the blood and found it in the bones. He fed several cats on enemata of milk, mutton, and chicken broth, and found slight alteration in weight. This demonstrated that they could readily take nutriment per anum, and that sufficient was absorbed to sustain life. In 1825 Dr. Beaumont began his celebrated researches upon Alexis St. Martin, showing effects of the gastric juice upon the foods.

In 1827 Dr. Tognoli made a series of experiments upon endosmosis and exosmosis. His experiments were confirmatory of Mr. Dutrochet. The experiments were made with the intestines and crops of fowls, as well as with the skin of a rat. The fluids used were gum-arabic solution, water, weak acid, and alkaline solution. He proved that endosmosis occurs in a certain membrane as long as its composition is normal. When it becomes putrid, exosmosis takes place very rapidly. He showed that endosmosis and exosmosis can go on at the same time. The denser of two liquids induces

† Philadelphia Journal of Medical and Physical Science, Vol. iv.

‡ American Medical Journal, 1827.

the rarer to form a current toward the former. By inverting the experiment he found the same thing would take place the other way through animal membranes.

In 1827 Dr. James Moultrie, Jr.,\* published a paper upon the use of the lymph. He concludes that lymph is not a residuary fluid transmitted from arteries to veins nor decomposed matter of tissue which it is the office of absorbents to remove. The origin, nature, and destination of lymph render it probable that it is a special secretion. Its office is to vivify the chyle, to augment the animalization of arterial blood, and, lastly, to produce all those effects which constitute the phenomena of reproduction, adhesion, etc. The lymphatics, according to him, are not the absorbents of the body.

In 1830 Dr. Edwin D. Faust,† of Columbia, S. C., made a series of experiments and observations on endosmosis and exosmosis of gases and the relation of these phenomena with the functions of respiration. He reviews the work done on the interchange of gases through animal membranes. He makes some experiments with endosmometer, using nitrogen, hydrogen, carbonic acid, and air. When gases are separated by a membrane, both of them pass through partitions, but one or other predominates. He then applies interchange of gases to respiration, showing there is a chemical combination.

In 1830 Dr. Samuel Jackson‡ published a paper upon the pulse and its modification. He shows that the frequency, force, and rhythm of pulse depend upon the heart; the volume of the pulse on the condition of the capillaries. The condition of the arteries modifies the tension of the pulse.

In 1830 Dr. J. K. Mitchell§ published a paper on the penetrativeness of fluids. After showing how gases penetrate membranes of gum elastic and also animal membranes, he made experiments with sulphuretted hydrogen, carbonic acid, nitrogen, and hydrogen. He shows very clearly that they penetrate the membranes of the body. He injects acetate of lead into the peritoneal cavity, and the sulphuretted hydrogen into the rectum. The animal dies and he finds a precipitate over the intestine. He then tries the interchange of different fluids, alcohol, ether, acid, and alkali water, etc., through different animal membranes, gum elastic, bladder, and human skin. He shows very well the penetrativeness of gases in organic tissue. The ratio of penetration for gases depends on them alone, while for liquids it depends on both the liquids and tissues.

In 1831 Dr. William V. Volk,|| of Providence, R. I., published a paper upon microscopical observation on portions of animal tissue, with additional experiments on endosmosis and exosmosis. His results were not in harmony with those of Dr. Togno. He ran his experiments for several days with crop and intestines of a fowl. He found endosmosis in intestines, and exosmosis in crop and cæcum. It is probable that the decomposition of his membranes caused his disagreement with the results of Dr. Togno.

In 1833 Dr. Maurice Fitz Gibbon¶ published a paper on the forces by which the blood circulates. He dissected several hearts to determine the arrangement of the muscular fibers.

In 1834 Dr. Samuel Jackson,|| of Philadelphia, published a review of the subject of absorption, with some experiments. The paper is a very lengthy and exhaustive one, and I shall only speak of a few points in it. According to him the skin absorbs, as do the lungs, stomach, cellular, and serous tissues. He speaks of Dr. J. K. Mitchell injecting into the pleural cavity solution sulphate of iron and prussiate of potash into the peritoneal cavity. He saw a blue color in the veins of diaphragm. He also speaks of vascular absorption, the part of absorption in nutrition, and the mechanism of absorption. Dr. Jackson exposed and ligated the external jugular vein in two places, applied prussiate of potash to wall of vein and obtained a blue

|| American Medical Journal.

¶ American Medical Journal, 1833.

color on treating lining of vein or serum with sulphate of iron. According to him they proved that lymphatics were not exclusively the only means of absorption. He states that dropsy is caused by defective absorption, that it is a vice of nutrition and impoverished state of the blood.

In 1836 Dr. J. K. Mitchell \* published a paper on penetration of gases. He repeats many experiments in a paper just noticed and shows that the laws of diffusion established by Mr. Graham, of Glasgow, do not apply to animal membranes of a closer structure than stucco.

In 1836 Dr. Robert E. Rogers,† of Philadelphia, published some experiments upon the blood. He found that exhaustion by his air pump had no effect on evolving CO<sub>2</sub>. A temperature of 212° F. does not displace carbonic acid. Carbonic acid is absorbed by exposing venous blood. The exposure of venous blood to oxygen, nitrogen, hydrogen, and nitrous oxide does not displace carbonic acid, although some of each gas (except hydrogen) is absorbed. When venous blood is put in a bag with access to an atmosphere of oxygen, hydrogen, etc., then more carbonic acid is given off.

In 1838‡ Dr. John D. Fisher, of Boston, published a paper upon the cerebellum, showing a loss of sexual sense.

In 1838§ Dr. John W. Draper published a paper on some mechanical functions, the coördination of the diffusion laws, by Professor Graham, and the experiments of Dr. J. K. Mitchell. This paper deals with diffusion of gases, and shows that peculiar mechanical functions depend on the condition of texture. They often, in appearance, are the generators of power. Endosmosis is a manifestation of capillary attraction and does not bear any peculiar relation to organization. There is no case on record where endosmosis has effected a real chemical change.

In 1839 Dr. J. J. Allison|| published experiments proving the existence of a venous pulse, independent of heart and nervous system, with remarks on contractility of veins in general. He made experiments upon animals, and noted that the venæ cavæ and pulmonary veins pulsate in four classes of vertebrates. Distension by blood is not necessary for their contraction. In 1839 Drs. C. W. Pennock and Moore ¶ published a paper upon the heart's action. Their experiments were made upon sixteen calves and sheep, Drs. Hardy, Stillé, George B. Wood, and Mr. Burns being present. The animals were knocked on the head with an axe. Artificial respiration being kept up by a bellows, the chest opened longitudinally, the heart observed and its sounds listened to by another member with a stethoscope. They determined that the impulse was synchronous with the ventricular contraction caused by apex striking chest wall. The blood is expelled from the ventricles by approximation of walls and not by contraction of apex toward base. During systole the heart performs spiral movements and becomes elongated. The ventricle contracts and the auricle dilates at the same time, occupying one-half the whole cycle of time. Diastole immediately follows systole, equal to one-fourth of cycle, the auricle diminishing by emptying blood into ventricles without muscular contraction. The remaining one-fourth is devoted to rest, near the termination of which the auricle contracts actively. The sounds of the heart are produced by motions of heart on its contents and not by striking against chest wall. Sounds were much louder when stethoscope directly applied to heart than when chest wall or lung is interposed. The sounds are more distinct when muscle is thin and contracts quickly. Hence clear flapping sound over right ventricle as compared with left. First sound impulse and ventricular systole are synchronous. Muscular contraction is the chief factor in its production, for it is heard in extirpated heart with auriculo-ventricular valves held up. Contraction of auricle, flapping of auriculo-ventricular valves, and rushing of blood may contribute to it. The second sound

\* American Medical Journal, 1836, p. 100.

† American Medical Journal, 1836, p. 277.

‡ American Medical Journal, 1840.

§ American Medical Journal, 1833.

|| American Medical Journal.

¶ Medical Examiner, 1839.

exclusively due to closure of the semilunar valves. The second sound is synchronous with diastole of ventricle. In 1839\* Prof. Joseph Henry was the first to graduate electrical currents by sliding the secondary coil in a groove to and from the primary, as is done in Du Bois-Reymond's inductorium.

In 1840 the medical faculty† of Lancaster, Pa., made some experiments upon the body of an executed criminal. Drs. John and Washington Atlee were among the observers; also Dr. J. K. Mitchell. They found that when the air taken from the lungs before and after execution was analyzed that the CO<sub>2</sub> increased and the oxygen diminished after the execution. In 1842 Dr. C. A. Lee‡ published a monograph on the thymus gland. Under the microscope the gland was seen to contain an enormous number of white blood corpuscles, and he believed its function to be closely connected with hæmotosis and chyfication.

In 1842 Dr. Blanchard Dogati§ reported a case of a girl, *at.* 16, having passed puberty, who went into a deep sleep, or "catalepsy," as he calls it, when acted upon by a magnetizer for fifteen minutes.

In 1847 Dr. Samuel Kneeland,§ of Boston, published an article upon the use of cold water for the prevention and cure of disease. He speaks of the use of cold baths in fevers and hydrotherapy in general.

In 1847 Dr. C. W. Pennock§ published a paper upon the frequency of the pulse and respiration of the aged. He made his observations in the Philadelphia Hospital. He excluded all cases with cardiac, pulmonary, or other disease. The observations were made four hours after meals, with the patient sitting or standing. He examined 170 men, ages from 50 to 90 years, and 203 women, ages from 50 to 115 years. The average age of the men was 64.09 years. Their average pulse was 71.83; average respiration, 20.51; ratio 1:3.5. The average age of the women was 70.57 years; their average pulse, 78.02; their average respiration 22.06; ratio 1:3.50. He concludes in this very valuable and scientific paper that the frequency of the pulse of the aged is greater than usually admitted. The respiration frequency of old age is equal to that of the adult middle age.

In 1849-'50 Dr. Bennet Dowler|| made some contributions to physiology. He cut the spinal cord of alligators and found movements in the head and in the parts behind the section. The head tried to bite when one came near it, and it winked. He argues that this was not reflex, because there was no contact. According to him the spinal cord movements were from memory and not reflex. Evisceration does not kill the alligator, the heart beating for hours. Ligature of the trachea kills this animal quicker than section of the spinal cord.

In 1848 Dr. Charles Frick,¶ of Baltimore, published his paper upon the blood, its amount of fibrin in different diseases.

In 1848 Dr. George Wymberly Jones, of Georgia, made an experimental inquiry into the correctness of Poisenille's theory of the purgative action of certain salts. He can not see why one should conclude that cathartics purge by means of endosmosis because the blood serum permeates an animal membrane to mingle with the sulphate of soda.

In 1849 Dr. James Blake, of St. Louis, gave a résumé of experiments to determine the quantity of blood by means of sulphate of alumina.

In 1849¶ Dr. J. Locke, of Cincinnati, gave us the principle of the electro-magnetic time marker.

In 1851 Dr. J. C. Walton published his famous researches upon the corpus luteum.

In 1852 Dr. Brown-Sequard gave us the great researches which he had worked out during the past eight years. They are too voluminous to abstract.

¶ Physiologische Methodik Gescherdlen.

In 1852 Dr. S. Weir Mitchell published a paper showing that feeding frogs upon sugar produced cataract.

In 1854 Dr. J. C. Walton published his paper upon the movement of the glottis in respiration, demonstrating that during normal respiration there is a constant and regular movement of the vocal cords by which the glottis is alternately enlarged and diminished.

In 1854 Dr. S. Weir Mitchell published a paper upon the relation of the pulse to the respiration. He finds the pulse rate lessened in inspiration and increased in expiration.

In 1854 Dr. Samuel Jackson gave us a paper upon the digestion of fatty matters by the pancreatic juice, confirming Bernard's work.

In 1855 Dr. William A. Hammond published a paper showing the relation of urea to uric acid. He showed that exercise increases urea and diminishes uric acid, while rest diminishes urea and increases uric acid. In his *Physiological Memoirs* he makes a number of urological contributions, such as the effect of alcohol and tobacco upon the constitution of the urine. He also has a paper upon the nutritive value of albumin, starch, and gum. Another paper is upon the effect of the injection of urea and other substances into the blood. He also contributes a paper upon the action of certain vegetable diuretics.

In 1855 Dr. Joseph Jones published a paper upon the kidneys and its excretion. He states that the amount of excretion depends upon the amount of the force and rapidity of the circulation; the activity of the skin, action of colon, activity of the respiration, *et altera*.

In 1856 Dr. Joseph Jones gave us a paper upon the digestion of albumin and flesh and the comparative anatomy of the pancreas. He confirms Bernard's work.

In 1856 Dr. Francis Gurney Smith made some experiments upon Alexis St. Martin, showing that acid of the stomach is lactic and that amylaceous materials are converted in the stomach into glucose. Dr. Dalton opposed this statement, asserting that the glucose existed in the bread used as food. To this statement Dr. Smith replied by feeding Dr. Brown-Sequard (after washing out his stomach) with arrowroot, which he soon vomited. Glucose was found to be present. No insalivation of the arrowroot was permitted.

In 1856 Dr. Joseph Jones, of Georgia, made a series of experiments, under the direction of Prof. Joseph Carson, on the action of saline solutions of different densities upon living animals and also the reciprocal action through dead animal membranes of serum, water, and saline solution. He concluded that the laws which regulate action of saline solution on living animals can not be demonstrated with dead animal membranes.

In 1856 Dr. Joseph Jones published another paper upon the chemical, physical, and physiological investigation upon the vital phenomena, structure, and offices of the solids and fluids of animals.

In 1856 Dr. J. C. Draper published a paper, "Is urea due to muscular motion?" and experimented upon the respiration.

In 1856 Dr. G. P. Camman published a paper upon the capillaries of the lungs.

In 1856 Dr. J. C. Dalton published a paper on the decomposition of iodide of starch.

In 1857 Dr. J. C. Dalton published his experiments upon the secretion of bile. He made 67 experiments upon animals, showing the different constitution of the bile in different animals, its reaction with gastric and intestinal juices, and lastly its mode of disappearance in the alimentary canal.

In 1857 Dr. Austin Flint, Jr., published a paper upon the phenomena of the capillary circulation.

In 1858 Dr. H. F. Campbell, of Georgia, was the first to announce the theory of reflex secretion and the excito-secretory system of nerves.

In 1859 Dr. J. C. Dalton published a paper upon the physical and chemical changes in the interior of the body.

In 1857 Dr. S. Weir Mitchell published his paper, "Effect of alcohol, glycerin, water gum, ammonia at the vacuum upon the exposed hearts of frogs, snapping turtles, and sturgeons."

In 1860 Dr. S. Weir Mitchell published his valuable monograph upon the venom of the rattlesnake.\*

In 1861 Dr. J. C. Dalton published a paper upon the cerebellum.

In 1861 Dr. Austin Flint, Jr., gave us a paper on the points connected with the action of the heart and respiration. His results are as follows: (1) The heart of the dog elongates during systole. (2) The natural stimulus of the heart beat is the blood, and the stimulus can not be supplied by water or any fluid of lesser density. (3) The excitation causing the reflex act of respiration is received from the general system and not from the lungs or heart. The excitation is due to a want of oxygen in the tissues and not to stimulating properties of venous blood.

In 1862 Dr. Austin Flint, Jr., published a paper upon a new excretory function of the liver, showing that cholesterin is removed from the blood and discharged from the body in the form of stercorin.

In 1862 Dr. Austin Flint, Jr., published a paper upon the glycogenic function of the liver.

In 1863 Dr. Austin Flint, Jr., gave us a paper upon the organic nitrogenized principles of the body.

In 1863 Dr. S. Weir Mitchell gave us a monograph upon the physiology of the respiration in cheloma.

In 1863 Drs. Hammond and Mitchell published their experiments upon corroval and NaO.

In 1867 Dr. T. R. Noyes published a paper upon the excretion of urea.

In 1867 Dr. S. Weir Mitchell gave us a paper upon the retrogressive motion in birds produced by the application of cold to the cervical spine.

In 1869 Dr. S. Weir Mitchell published a paper upon the physiology of the cerebellum.

In 1869 Dr. S. Weir Mitchell published a paper upon the insusceptibility of pigeons to opium.

In 1870 Dr. Wm. Lusk published a paper upon the origin of diabetes.

In 1870 Dr. H. C. Wood published a paper upon the physiological action of viridia, veratroidia, and veratria of commerce.

In 1871 Dr. H. C. Wood published a paper upon the action of atropia on birds.

In 1871 Dr. H. C. Wood gave us a paper upon nitrite of amyl, its physiological action.

In 1873 Dr. H. C. Wood gave us a paper upon the action of atropine, and during the same year a paper upon the section of the vagi and the effects of emetics and cathartics.

In 1874 Dr. Austin Flint, Jr., published a paper upon the mechanism of reflex nervous action in normal respiration.

In 1874 Dr. James Putnam published a paper upon the physiology of the cortex cerebri.

In 1874 a monograph upon cocaine, veratria, and gelsemium by the speaker.

In 1874 Drs. H. P. Bowditch and Minot published a paper upon the influence of anæsthetics on the vasomotor centers.

In 1876 Dr. H. P. Bowditch published a paper upon ciliary motion, and in the next year a paper upon the growth of children.

In 1878 Dr. W. H. Klapp published a paper upon the action of strychnia and Dr. James Munro Murray upon the action of aconitia and napellina.

Prof. Robert Meade Smith in the same year published a paper upon the action of sanguinaria.

In 1879 Dr. Austin Flint, Jr., published a paper, Experiments and reflections on animal heat.

In 1879 Prof. E. T. Reichert\* published a paper on apomorphia.

In the same year Drs. Martin and Hartwell published a paper on the respiratory function of the intercostal muscles.

In 1879 Dr. R. H. Chittenden published a paper on the formation of hydroxanthin from albumin.

In 1879 a paper by speaker on the spinal cord.

In 1879 Drs. Bowditch and Garland published a paper on the effect of respiratory movement on the circulation.

In the same year Dr. Sewall published a paper on the effect of two succeeding stimuli on muscular contraction.

Dr. C. Sibley also published in this year a paper on heat dyspnoea.

As the titles of papers have become too numerous to mention, I shall refer to the number produced each year, as compiled from the Index Medicus. In 1879 there were 36 articles on physiological subjects; 1880, 52; 1881, 21; 1882, 39; 1883, 19; 1884, 26; 1885, 22; 1886, 20; 1887, 44; 1888, 38; 1889, 25; 1890, 17. Having reviewed the past labors of American physiologists, it remains to speak briefly of the present.

The present state of physiology in the United States is in a very promising condition. Unlike England, we are not hampered by licenses and restricted in methods in experimentation. The antivivisectionists are, however, still active, especially in the State of Pennsylvania. It seems to me that the unanimous indorsement of vivisection by the Pan-American Congress would be quite appropriate. The well-furnished laboratories at Boston, Worcester, New Haven, New York, Philadelphia, Baltimore, and Chicago offer great opportunities for anyone endowed with any special love for this work. I say special love, for without it you will not labor long at it, as it is exhausting both financially and physically. As to the future, everything is of a rosy hue. With Mæcenas giving from five to twenty millions to start universities, it ought not to be difficult to have fellowships in physiology at our universities, which should be open to competition, and held as long as the party gives evidence of progress. They should be of sufficient value to attract able young men. At least \$1,000 should be the amount of salary. With a few fellowships in physiology the laboratories would be in continual activity, and thus physiological enthusiasm would be stirred up among all concerned. The laboratories themselves should be endowed with a perpetual income, that new apparatus may be built or purchased, for no laboratory of physiology will ever be within any possibility of supporting itself. Money is especially needed to purchase animals, for simians are expensive, but results obtained from them are greatly to be desired, as they more nearly approach us in general constitution. After all, the physiology of man is what we need in our practice as physicians.

---

## THE PHYSIOLOGICAL BASIS OF THERAPEUTIC ACTION; AN EXPERIMENTAL INQUIRY.

By THOMAS J. MAYES, A. M., M. D., of Philadelphia, Pa.,

*Professor of Diseases of the Chest in the Philadelphia Polyclinic, and Visiting Physician to the Rush Hospital for Consumptives, of Philadelphia.*

In this paper an effort will be made to explain some of the fundamental principles of medicinal action on a physiological basis. I think from the present standpoint of physical science we have great reason for believing that every phenomenon in nature may be viewed as the effect of force, and that therapeutic action, as a part of the grand chain of natural phenomena, becomes intelligible only when it is

---

\* Philadelphia Medical Times.

reduced to the same terms. This is indeed demanded by the modern doctrine of the conservation of force. From this it follows that any system of therapeutics which fails to take into account the relation between drug action and the outer world must necessarily be imperfect and limited in its practical application. The fireman looks upon the coal with which he fires his engine as the ultimate source of heat, while the philosopher regards the same material as a storehouse of force in the accumulation of which an equal quantity of force was consumed in the sun thousands of years ago, and that ultimately the force which is concentrated here is but a part of the force which pervades the universe. That which is true here is also true of therapeutic action. Heat is applied to the animal organism in various ways. Applied in moderate quantity to a beating frog's heart, as Kronecker has demonstrated, it accelerates the pulsations of this organ, but when applied in greater quantity its pulsations are arrested. When applied in excess, as in the form of steam, or the hot iron, it destroys animal tissue. Now, he who takes a disconnected view of these effects necessarily concludes that heat possesses at least three different properties, (1) that of a stimulant; (2) that of a depressant; and (3) that of an escharotic. But he who believes in the universality of force knows that heat is force, and regards these different phenomena as the varying effects of this force applied in varying quantities.

About fifteen years ago I ventured to express the opinion on a purely inductive basis that our therapeutic agents behave like physical forces, inasmuch as in the case of heat they enhance vital action in small and depress it in large quantities. Since then I have investigated this question from an experimental standpoint and believe that I have succeeded in verifying this opinion of the action of a large number of our most important therapeutic agents, at least so far as this stands related to the behavior of the frog's heart. The method which I employed was the following: A frog's heart was securely adjusted to a double canula and then attached to a Kronecker-Bonditch heart apparatus. In this position the heart may be filled with any desirable fluid, and the action of this on the heart may be estimated by the elevation or depression of the tracings which it records on the smoked surface of a revolving cylinder. If it is filled with a 2 per cent solution of blood and receives regularly minimum induction shocks it will continue to beat for many hours in succession, and the elevation of its tracings under such conditions is taken as a standard of the heart's best work. This being constant under the action of the blood solution, any deviation from this normal line which may be brought about by the addition of an agent to the blood solution must hence be ascribed to the influence of such agent.

Before going any further, I wish it clearly understood that in these experiments we must not view the frog's heart as being simply the representative of the heart's function in general, but as that of an isolated organism through which, on account of its vital simplicity and tenacity, and of its peculiar physiological adaptability, we are able to demonstrate and measure the action of different substances on organized animal life.

These experiments, as has already been stated, were undertaken with a view of finding whether a drug, in any quantity, added to the 2 per cent blood solution, has the power of producing a higher tracing than that which can be obtained from the blood solution alone. After many trials it was found that all the drugs which were investigated showed such an action in certain doses, which, on account of their diminutiveness, are named minimum doses. On the other hand, it was found that larger quantities paralyzed the heart's action to such a degree that its pulsations were arrested either in systole or diastole, according to the nature of the drug. The quantity which produced this effect is called the maximum dose. This double action is well exemplified in the following tracings which were obtained from sodium hydrate. The minimum dose of this drug was found to be 1:160,000, i. e., one part of sodium hydrate to one hundred and sixty thousand parts of blood; and the maximum dose, 1:1000, i. e., one part of sodium hydrate to one thousand parts of blood.

## TRACING OF SODIUM HYDRATE.

These tracings show us that the addition of a minimum dose of sodium hydrate to the blood produces higher heart beats than are given by blood alone, and that a maximum dose arrests the heart in systole. This is positive evidence that sodium hydrate when administered in suitable doses is capable of pushing the function of the heart over and above the point which it is capable of exerting in its ordinary state of nutrition; and that on the other hand the same agent when given in large doses has the power of completely inhibiting the heart's action. Now, that which has here been shown to be true of the action of sodium hydrate is also true of the behavior of the following substances which were included in this research, and which are here given in alphabetical order: Acetic acid, aconitine, alcohol, aloin, ammonia, atropine, apomorphine, brucine, ammonia, caffeine, cannabin tannate, carbolic acid, chloric ether, chloroform, chloral hydrate, cocaine, colchicine, conium, curare, delphinine, digitalin, ether, ethyl bromide, gelsemine, guaranine, hydrastine, kairine, lactic acid, lycopin, morphine, corrosive chloride of mercury, piperidine, pilocarpine, potassium and its salts, quassin, quinine, resorcin, sanguinarine, salicin, saponin, spirit of nitrous ether, strychnine, sodium and its salts, theine, and veratrine.

In this connection it is worthy of note, as one of the many interesting phenomena which developed during this investigation, that while large doses would invariably arrest the heart's action, yet this arrest was brought about in either one of the two ways. Such agents as the acids, the potassium salts, aconitine, strychnine, cocaine, curare, chloroform, ether, etc., arrested it in diastole; while the sodium salts, ammonia, digitalin, morphine, quinine, caffeine, theine, etc., arrested it in systole.

These experimental results give us the assurance that all these drugs have at least two kinds of effect on animal life—in minimum doses they exalt normal vital action, and in maximum doses they depress or annihilate the same. Further investigation in the same direction brought out the fact, too, that minimum doses are directly antagonistic in their action to maximum doses. For example, a maximum dose of chloroform, which was found to be one part to five hundred parts of blood, almost entirely inhibits the action of the heart, but when a minimum dose of atropine, which was found to be one part to one hundred and sixty thousand parts of blood, is added to this dose and administered at the same time the tracings may be as high, or even higher, under this combined influence than they are under the influence of minimum doses of this agent, or under the blood itself. This is well shown in the following tracing obtained from chloroform and atropine. The first part of the tracing (*a*) was produced by atropine in a minimum dose, the second part (*b*) by chloroform in maximum doses, and the third part (*c*) by combining a minimum dose of atropine and a maximum dose of chloroform. The same is true of chloroform and strychnine, of atropine and strychnine, and of many other agents as will be seen from the following tracings:

These examples not only give us experimental proof of the power of interference of one drug with the action of another, but they demonstrate the fact how a therapeutic force may be able to overcome and successfully resist the action of disintegrating forces. If we look beneath the surface of these phenomena we find at work here two forces, which, on being properly adjusted, become antagonistic to each other in their action on organic tissue, the one tending to enhance or to elevate, and the other to depress the function of the latter. These antagonistic effects are displayed as decidedly by drug interference as if they were produced by the two mechanical forces of attraction and repulsion, and they give us an exact and measurable demonstration of the power which drugs exert in supporting and preserving life when attacked by adverse forces. Now, if we admit that disease is but the manifestation of the action of morbid forces—forces which move in a direction inimical to health—and if we agree to substitute these in place of the operation of maximum drug doses, as given in the above illustrations, we have a clear picture before us as to the manner in which drugs combat disease, viz, by interference. Now, in what does this principle

of interference consist? What, in other words, is the intimate nature of the combat between drug action and disease? In explaining this we must, of course, take into consideration the fact that in a broad physiological sense all the textures of the animal body are in a state of continual molecular motion, which is maintained principally by internal chemical changes, and that so long as the molecular motion of each texture harmonizes with that of every other, health is the result; but that as soon as perturbation arises among any one or a number of these forces disease must follow. It is readily seen, therefore, how molecular motion may be maintained and enhanced in the body by the introduction of substances, like albuminous and carbonaceous foods, which we know undergo chemical change and apply the force thus arising to this purpose; but how forces—forces of a mechanical nature and which are antagonistic to the bodily forces—can enhance molecular activity is less easily seen, for on the surface it appears as though forces of such a character would naturally tend to produce disintegration under all circumstances.

But that aggressive or antagonistic forces have the power of augmenting healthy molecular motion, under certain conditions, will appear patent from the following observations: If, for example, gentle friction or massage is applied to the body the molecular activity of the latter is at once aroused to its utmost physiological capacity. We have here the antagonism of two kinds of forces—the force of friction or of massage, and those of the tissues to which these were applied—moving in different directions, but which are governed by the same fundamental physical laws, viz, motion takes place in the line of least resistance, and action and reaction are always equal; or, in other words, one force acting on another always calls forth a corresponding reaction. Then, when two forces of equal strength meet each other from opposite directions rest is produced. This is exemplified in the production of darkness by two waves of light. When, however, two forces of somewhat unequal strength come in conflict with each other, the stronger will cause the weaker to move in a direction parallel to its own and to a point where a mutual balance takes place; and although the latter may tend to rebound and to assume its former position, yet, through the operation of a series of such impactions, it will be finally forced to seek a new or another state of equilibrium in which it will remain after the attacking force has ceased to act.

The *modus operandi* of this is well illustrated in the following example: When a gentle gale blows over a wheat field the stalks of grain are generally blown into a leaning position which is more or less permanent; but a steady and continuous wind of equal force applied afterwards from an opposite direction will cause the stalks to become straight again—to resume and to remain in a normal equilibrium after the latter force has ceased to operate. This not only illustrates the intimate nature of the beneficial action of massage and of friction, but that of many other agents, of which strychnine, quinine, atropine, and digitalis in suitable doses are good examples, and shows how the effects of these therapeutic measures, although moving antagonistically to the bodily forces, become permanent in their influence. Moreover, if we view our therapeutic agents in the light of forces, we are not only enabled to explain their action in varying doses and the antagonism of these, as has been done, but we can also account for the fact that many, if not most of our medicines, prefer to act on one tissue rather than on another; or, in other words, we can say why cathartics act on the intestinal canal, emetics on the stomach, digitalis, strophanthus, and caffeine on the heart, cantharides and copaiba on the urinary tract, etc. For the law of the “physiological division of labor” means that the integrity of the body is maintained by many diverse forces or functions within itself, each force or function having its own particular duty to perform; and if an antagonistic force is introduced among so many different forces, widely varying results must be produced—some physiological forces being disturbed, while others are altogether untouched—those showing the greatest opposition or antagonism being most strongly influenced. The phenomena of acoustics give us a fitting illustration

here. Two sounds interfere with each other in proportion to the disparity which exists between them—a small difference causing a slight degree of interference, and two diametrically opposite and equal sound waves will annihilate or neutralize each other, and cause perfect silence. Again, if the tone of E flat is produced simultaneously with the chord C, E, and G, the former will only interfere with the tone E, because it forms a discordant relation with this tone, and an agreeable relation with the other two sounds. The wave E flat therefore antagonizes the wave E only, and leaves the other two waves undisturbed. This principle of action makes it clear, then, why different therapeutic substances should affect different organs; and the same principle carried further also explains why some agents act only on one part, while others act only on another part of the same tissue or organic apparatus. The nervous system, for example, is composed of the same general anatomical elements throughout and possesses the common function of generating and transmitting impulses; yet morphine, cocaine, strychnine, curare, pilocarpine, atropine, hyoscine, gelsemine, hydrastine, and ergotine all affect this system in different regions and in different ways.

Now, while it is true that there is a general uniformity of structure and function of the nervous system, it is also true that there exists special structural and functional differences in this mechanism which are brought about by special requirements and conditions. Thus it is the function of motor nerves to transmit motion, but it is also the function of different parts of motor nerves to transmit different degrees and kinds of motion. The impulses which are transmitted by the nerves of general sensation differ from those which travel along the nerves of special sensation. The pneumogastric nerve supplies the lungs, heart, stomach, liver, and intestines, and its variable and extensive distribution is evidence that the impulses which are conveyed by its branches must differ greatly, for the impulses which have the power of maintaining the function of the heart are not adapted to the necessities of the stomach, nor are those which are essential to the support of the function of the liver suited to the wants of the respiratory apparatus, or to those of the intestines, showing how, on the score of the principle of interference, a therapeutic force may affect a special branch of a nerve and leave all the other branches unaffected.

The fundamental principles of drug action, therefore, resolve themselves into (1) stimulant effects of small doses; (2) depressant effects of large doses; and (3) elective affinity. From this it follows that whatever the elective affinity of a drug may be, the dose which is administered will decide whether it enhances or depresses the function of the organ on which it acts. Hence, when we come to classify the action of drugs, we have stimulants and depressants of every important organ in the body. Thus we have stimulants and depressants of the general nervous system and of special parts of the same, of the heart, lungs, liver, intestines, kidneys, skin, etc., which demonstrates that the old grouping of the action of drugs into stimulants, tonics, narcotics, expectorants, emetics, cathartics, cholagogues, diuretics, diaphoretics, etc., is the only scientific and natural classification. Time and space forbid me, however, from going into the details of this part of my subject any further, and after having run the risk of wearying you nigh unto intoleration I trust I may indulge in the hope that this feeble effort in placing the study of therapeutics on a firmer and more scientific basis than it has heretofore occupied may give an impulse to future inquiry in this direction.

---

#### DISCUSSION.

Dr. MacCallum observed that the heart is developmentally the oldest organ in the body, and from the point of view of structure one of the most highly differentiated. One would expect, therefore, that drugs would affect this organ, to a certain extent, differently from the way they would affect a more simple organ, like a simple

cell or a collection of simple cells. To make a fundamental classification of drugs according to their action, an organ such as a simple cell or group of simple cells should form the basis of experiments. Dr. MaCallum has been in the habit of urging the use of ciliated cells for this purpose, and the possibility that they could be studied in this respect by means of Engelmann's Ciliary wheel, no doubt, when some experienced experimenter should endeavor to carry the use of that instrument beyond that to which Engelmann subjected it, modify it to show finer and more delicate results than the machine gives as it is now constructed. Dr. MaCallum referred to the excellence of the graphic tracings which Dr. Mays obtained to support the contentions of his paper and expressed the pleasure with which he listened to Dr. Mays's paper.

Dr. Mays, of Philadelphia, said he had nothing to add except to warmly thank the members of the section for the kind manner in which they received what he said. He would say, however, that he believed that the experiments of Engelmann, at least in part, confirm the result which he had obtained from the heart.

---

#### SOME OBSERVATIONS ON NORMAL GROWTH AND DEVELOPMENT OF THE HUMAN BODY UNDER SYSTEMATIZED EXERCISE.

By HENRY G. BEYER, M. D., Surgeon, U. S. Navy.

Some of our best naturalists inform us that the first living things on this globe must have been microscopic, monocellular organisms, inhabiting the surface of the great oceans and leading a free-swimming existence, like the protozoa, their direct descendants, of the present day. Most all of them, furthermore, agree, I think, that there could have been no departure whatever from this monocellularism of existence—no aggregation of cells to build up more complicated organisms could have taken place until some of these protozoa began to assume a sessile form of existence at the bottom of the ocean, whereby nutriment came to them in the current flowing by them, instead of their having to everlastingly hunt for it, and thus expending all their available energy in this direction only. The law of growth and development, in other words, depends on alternate rest and activity, and is one of the oldest and most fundamental in its relation to life in general. Where and however we may study life, whether it is during the embryonic conditions of the higher organisms, or in the adult conditions of both high and low forms of life, we recognize everywhere the existence of resting stages alternating with stages of activity. Thus, in the higher animals, we find the corpuscles of blood and lymph ever active and in constant motion microscopically small. According to the laws of growth they must remain so, but at the bottom of this sea of blood and lymph we find a number of sessile organs, aggregations of cells belonging to the same organism, and made possible only under the same law of alternate rest and activity.

Further reflection and observation have shown this great and fundamental natural law to be at the bottom not only of the evolution of all living forms at present existing, but we can observe it and study its influence in every individual living being. It is consequently clear, then, that growth and development of the human body must be subject to the same unerring laws, and in order that they shall exert their most favorable influence on the formation of that body, they must be duly observed and properly administered. Exercise, alternating with rest, then, are the two most important factors with which scientific physical training will have to deal for the purpose of producing the highest results. Speaking physiologically, there is no difference between the labor performed by the workman and that performed by the gymnast. Both the wood-chopper and the football player do muscular work. But the one has his exercise at his own hours and follows the laws of hygiene, diet, and rest, while the other does not do so, nor can he do so, and we can easily

understand why exercise strengthens the one and wears out the other. Neither does it make any difference to the contracting muscle whether it is made to contract according to the Swedish system, or the German system, or even the American system; as long as it is caused to contract thoroughly and energetically and is allowed to rest after contraction, it will develop and grow in spite of any system.

For a number of years past a system of anthropometric measurements has been introduced into some of our best schools and colleges for the avowed purpose of watching, with more accuracy and scientific exactness than heretofore, the processes of growth and development of the rising generation of Americans as they march through the college gymnasia of these respective institutions. The highest credit and praise are due to the pioneers in this laborious undertaking. The large number of finely equipped gymnasia that have sprung up everywhere like magic must be looked upon as the direct results of their most excellent missionary work in the cause of physical education. But although growth and development are primarily physiological subjects, and therefore should greatly interest physiologists, very little interest has, so far at least, come from that direction. Most of the papers that have appeared, ever since the time of the introduction of these measurements, are most decidedly of more anatomical and anthropometrical interest than of physiological value, and, so far at least, anthropometry has been made an end rather than a means. However, since we have at last succeeded in discovering not only the perfect typical and ideal man, but the woman also, and have had them both safely landed at Chicago, where the two are now supposed to dwell in unison, if not mutual admiration of one another, there is some hope that the leaders in physical education may turn their talents to the much neglected physiological side of this question. Indeed, a beginning has already been made and I have in my possession three papers of the utmost physiological importance as regards physical education. The first of these papers is "The Growth of Children, Studied by Galton's Method of Percentile Grades," by H. P. Bowditch; the second is entitled "The physical basis of precocity and dullness," by W. T. Porter, and the third is "Observations on the results of the pedagogical gymnastics of the Luig system," by Claës J. Enebuske.

The object I had in view in preparing this paper is partly for the purpose of inviting more interest in this subject on the part of physiologists, and partly also to add some observations of my own, made on 50 naval cadets, as ascertained by two successive measurements made at certain intervals, namely: The first measurements were taken in September, 1892, and the second in April, 1893, the time interval between the two measurements being, therefore, about six months. From the whole number of measurements that are usually taken of each individual only a few were selected for consideration here, since to discuss them all would rather detract from the few more important ones selected for our purpose, and would add nothing to the physiological value of the results that may be derived from them all. These items are: (1) The height, (2) the weight, (3) the lung capacity, and (4) the total strength. We will also take into consideration the vital index, the power index, the strength-weight index, and the vital-strength-weight index, which form very important indices, introduced by Enebuske, and all deducible from the first four items. As regards the nature of the gymnastic exercises which the cadets took during the interval of these measurements, I could not say that any one particular system of gymnastics was followed out to the exclusion of every other system. From the point of view of the physiologist there can be but one system, namely, that of common sense and judgment, having for its sole purpose the gradual, progressive, harmonious, and symmetrical development of the individual according to his needs and according to physiological laws, and in this process the instruments used are the subordinate means to the end, no matter to what particular system of gymnastics they may belong.

A brief outline, however, of these exercises seems called for. Thus, during the first month calisthenics or free movements were daily employed, and breathing exercises were practiced on the different chest weights. During the second month

dumb-bells, Indian clubs, and boxing were introduced. During the third month running, jumping, and vaulting were begun. During the fourth month rope climbing, rope jumping, horizontal and parallel bar exercises were done. After that the out-of-door drills began, and the cadets only exercised in the gymnasium in rainy weather, some also doing special exercises prescribed for them in accordance with their special needs and requirements. This is, in brief, the course that was pursued. All had infantry drill, but none had any fencing, which is begun after the first year of their stay at the Academy. The time devoted to gymnastic exercises was one hour per day, except Wednesday, making five hours per week in all, the remainder of the time, of course, being devoted to mental work, with the usual intermissions for recreation common to all schools. The cadets are also taught dancing during the winter, and the weekly Saturday night cadet hops continue throughout the academic year, not all the cadets, however, taking part. It is perhaps but fair to state that the changes that are recorded in the following tables as having taken place in the cadets are not and can not be looked upon as strictly comparative, nor as due to the gymnastic exercises alone, for in order to make them strictly comparative it would require the records of 50 other cadets of the same age and living under the same conditions that had not taken this exercise, and, besides, there were other exercises taken outside the gymnasium and belonging to the Academy curriculum not strictly to be classified as gymnasium exercises. We will begin, then, first with the consideration of their height and see what changes we can detect in that, also what possible standard we may derive from a larger number of cadets that had entered previously to 1892. The records of this Department place at my disposal, so far, two hundred and thirty entries of cadets whose height was accurately measured and recorded upon their entry into the Naval Academy. Inasmuch as there exists no standard for admission to the Academy as regards height for a certain age, except that the candidate, regardless of his age, shall not measure less than 5 feet or 1,624 mm., that he shall be sound and not less than 15 years of age, it seemed promising of some interest to find out just how the average height of the entering naval cadet under this plan compared with that of other schools and colleges from which data for comparison are at hand, taking, of course, the age into consideration in making this comparison.

The following table shows the distribution of the two hundred and thirty cadets, as regards height, in millimeters.

TABLE 1.

| Millimeters. | Number of observations. | Millimeters. | Number of observations. |
|--------------|-------------------------|--------------|-------------------------|
| 1,850.....   | 2                       | 1,625.....   | 23                      |
| 1,825.....   | 1                       | 1,600.....   | 8                       |
| 1,800.....   | 15                      | 1,575.....   | 2                       |
| 1,775.....   | 19                      | 1,550.....   | 2                       |
| 1,750.....   | 27                      | 1,525.....   | 0                       |
| 1,725.....   | 34                      | 1,500.....   | 0                       |
| 1,700.....   | 36                      | 1,475.....   | 1                       |
| 1,675.....   | 28                      |              |                         |
| 1,650.....   | 32                      | Total .....  | 230                     |

The next table shows their heights, arranged in percentile grades varying from 5 to 95 per cent, as they compare with those of the Amherst students aged 17 years, and those of the Boston schoolboys aged 16, 17, and 18 years, respectively. The average age of the two hundred and thirty cadets is 18 years.

TABLE 2.

[Millimeters.]

| Percentile grade.      | Average age. | Number of observations. | 5.    | 10.   | 20.   | 30.   | 40.   | 50.   | 60.   | 70.   | 80.   | 90.   | 95.   | Average. |
|------------------------|--------------|-------------------------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|----------|
| Cadet.....             | 18           | 230                     | 1,587 | 1,611 | 1,628 | 1,650 | 1,656 | 1,678 | 1,681 | 1,725 | 1,726 | 1,751 | 1,775 | 1,679    |
| Amherst students.....  | 17           | 2,230                   | 1,625 | 1,647 | 1,674 | 1,692 | 1,710 | 1,724 | 1,739 | 1,756 | 1,776 | 1,804 | 1,827 | 1,726    |
| Boston schoolboys..... | 18           | 65                      | 1,602 | 1,627 | 1,653 | 1,666 | 1,681 | 1,696 | 1,710 | 1,725 | 1,749 | 1,788 | 1,802 | 1,684    |
| Do.....                | 17           | 128                     | 1,567 | 1,591 | 1,630 | 1,653 | 1,669 | 1,686 | 1,705 | 1,729 | 1,746 | 1,780 | 1,801 | 1,684    |
| Do.....                | 16           | 233                     | 1,544 | 1,573 | 1,607 | 1,634 | 1,656 | 1,677 | 1,692 | 1,707 | 1,722 | 1,756 | 1,783 | 1,665    |

This table would show that the height of the naval cadet is considerably below that of the Amherst student, as well as that of the Boston schoolboy, at the same average age, and at the time of his entrance into the Naval Academy. The figures from the Amherst students were derived in part from Tables 5 and 7 of the Anthropometric tables published by Professor Hitchcock in 1892; the age was taken from Table 5 and the percentile grades from Table 7. The figures of the Boston schoolboys were obtained from Prof. H. P. Bowditch's work on "The Growth of Children, Studied by Galton's Method of Percentile Grades," published in 1891.

This comparison, however, is perhaps not perfectly fair, since the above two standards were compiled from part of our population noted for their height, while the cadets come from all parts of the country; they are, however, the only ones so far published, and consequently there was no choice in the matter of selection. The height of the average Yale student, according to Seaver's tables, at the age of 18 years, is given at 1,664 mm., and in accordance with this the average naval cadet would come out from 14 to 15 mm., or about three-fifths of an inch taller than the Yale student of the same age. Since Yale College is a larger school than Amherst, and since it derives its students from a larger territory than the latter, the average height of the Yale student is lower, probably on this account, and approaches more nearly the national average standard. As compared with the Boston schoolboy's the naval cadet of 18 years of age approaches more nearly the 16-year-old boy in height than the 17-year-old one. The 50 percentile grade of the height calculated from the two hundred and thirty cadets, at an average age of 18 years, is 1,678 mm., and the same grade of the Boston schoolboys, at an average age of 16 years, is 1,677 mm., or one millimeter less than that; while the average height of the cadets is 1,679 mm., and that of the schoolboys is 1,665, or 14 mm. less. The 18-year-old Boston schoolboy, measuring 1,695 mm. in height, is therefore 16 mm. in advance of the average height of the naval cadet, and the naval cadet is about 15 mm. taller than the Yale student of the same age.

Heights will probably always form one of the most important indices in our calculation and judgment of the physical possibilities of the man. Long bones naturally imply the existence of long muscles to move them, and there seems to be more room in a large frame also for the circumferential growth of the muscles than there is about a small, contracted framework. A capacious thorax, furthermore, will contain a larger lung, implying a greater lung capacity than a smaller one.

In the adjoining two tables of the heights of the fifty cadets, under more special consideration here, it will be noticed that each one of the two tables represents the measurements of twenty-five. Since this division of them is not merely accidental, but purposive, and will appear throughout this paper, it is necessary at the outset to state how and upon what ground this division was made. The principle in accordance with which the total number of cadets was divided is the amount of *increase in total strength* that took place in all between the first and second measurements. Table A contains all those whose increase in total strength was 100 kilos or less, and Table B contains all those whose increase in total strength was above 100 kilos,

Table of heights.

| 13 ..... | 16 7  | 1,754 | 1,754 | 0  |           |       |       |       |     |
| 14 ..... | 16 3  | 1,786 | 1,792 | 6  |           |       |       |       |     |

On comparing the two tables we will find that their various ages average up about the same, namely, 18 years. We find, also, that their increase in height is very nearly the same on the average, but the average height of those on Table A is 13 mm. below that of Table B. Now, the question might well be asked, Is it a mere coincidence, or is it of a certain significance that the members of Table B, who were slightly taller in the beginning than the members represented on Table A, had their total strength increased so much more than the members of Table A, all of them living under the same identical conditions? This question will be more fully discussed in connection with the tables of total strength to be presented later on. The average height, then, of the 50 cadets, at the beginning, and as ascertained by the first measurement, is 1,721 mm., and toward the close of the six months, as ascertained by the second measurement, it is found to be 1,729 mm., showing an increase in the average height of 8 mm., or about one-third of an inch. At present there exists no standard of comparison of the annual or semiannual growth of boys at all ages. An approximation to such a standard of development in height and weight for the pupils of the Boston public schools has been published in the above-mentioned work of H. P. Bowditch for a period of from 5 to 17 years. But inasmuch as Bowditch has shown that this increase is irregular and grows smaller the nearer the individual approaches to its destined maximum size, in order to fairly compare the growth of our cadets we ought to have a standard giving the increase in height above the age of 18 years, this being the average age with which we started. On looking over the tables of Yale students published by Seaver, I find that the height given for students aged 18 years and 6 months, which period would exactly correspond to the average ages of our cadets at the time of the second measurement, is 1,687 mm. or 23 mm., above the height given on the same tables

for 18-year-old ones, and which is 1,664 mm. According to these tables, then, the semi-annual increase in height from 18 to 18½ years would be 23 mm., or nearly 1 inch, for Yale students.

On examining the table of ages of the students at Amherst College, published by Hitchcock, I find that the height given for students of 18 years and 19 years of age is exactly the same, namely, 1,733 mm., apparently indicating no growth at all during the period between 18 and 19 years. Thus it must be admitted, until we have arrived at an exact standard of growth from year to year for all ages up to the twenty-second year of age, it is impossible to state whether the average increase of 8 mm. ascertained for our cadets is above or below the amount that it should be. One thing, however, seems to be clearly established by our tables of comparison alone, and that is this: The average height of the 50 cadets that entered the Academy in the fall of 1892 being 1,721 mm., it is 42 mm., or 1½ of an inch, higher than the average height of the 230 cadets who had entered during the last four years, and which is 1,679 mm., as may be seen on Table No. 2.

Annual growth tables, to be of value as standards of comparison, should be published from all the schools and colleges in all parts of the country, and the standards calculated for each year, or fraction of each year, during the entire period of growth. This, I hope, may soon be done, for there is no lack of material on hand now to work them out.

## WEIGHTS.

In the adjoining two tables of the weights, the same division of the 50 cadets is presented and carried out according to the same principle as was done in the two tables of the heights, namely, 25 on each table, Table A of the weights presenting the records of the same cadets as Table A of the heights, and Table B of the weights presenting the records of the same cadets as Table B of the heights.

Table of weights.

| 9.....  | 18 0  | 60   | 60.5 | 5.5 | 23.....   | 16 3  | 57.7 | 64.2 | 6.5 |
| 10..... | 19 0  | 66.5 | 72.3 | .8  | 24.....   | 16 4  | 52.5 | 59   | 6.5 |
| 11..... | 19 0  | 67   | 75   | 8   | 25.....   | 19 7  | 71   | 75.2 | 4.2 |
| 12..... | 17 8  | 70.6 | 75.3 | 4.7 |           |       |      |      |     |
| 13..... | 16 7  | 53   | 56   | 3   | Averages. | 18 0  | 60.9 | 64.9 | 3.9 |
| 14..... | 16 3  | 56.9 | 61.8 | 4.9 |           |       |      |      |     |

On looking at the averages of these two tables, it will be noticed that Table A gives 1.8 of a kilo less than Table B at the start, and that this difference between the two tables grows still greater at the second measurement, when it is found to be 3.2 kilos. The average increase of the first 25 cadets is 2.6 kilos, and the average increase of the second 25 is 3.9 kilos, or 1.3 kilos more. Both averages added together give for the entire number of cadets an average of 60 kilos at the time of the first measurements, and 63.3 kilos for the second measurement, amounting to a semi-annual increase in weight of 3.3 kilos.

From the observations recorded in the paper by Prof. W. T. Porter, of St. Louis, it would appear that precocious individuals are taller as well as heavier, and furthermore that the difference in weight between dull and precocious boys grows greater as they grow older. Since, then, the first 25 cadets, as we have seen so far, are smaller, lighter, and less strong than the second 25, I have examined their examination marks in order to see how Porter's results are borne out here, although our number is not very large. On adding up all their marks and dividing the sum by 25, those of Table A give 57, and those of Table B give 59 as the average, apparently confirming Porter's observations. On turning to Seaver's tables of Yale students, I find the average weight given for 18 years to be 55.4 kilos, and the weight for students of 18 years and 6 months to be 57.6; while the Amherst tables give 61 kilos for the 18-year-old student. The weights of the cadets, therefore, seem to be higher than those of Yale students, and about the same as those of the students at Amherst. So far, then, we have found not only that the members of Table B were taller, heavier, and stronger at the start than the members of Table A, but also that the increase in these qualities was greater as time went on, and in spite of the conditions being identical.

LUNG CAPACITY.

On looking at the two adjoining tables of the lung capacity we will find, although the average lung capacity on Table B is greater than that on Table A at the start, the average increase is about 20 cubic centimeters less on Table B than on Table A. The average lung capacity of the 50 cadets at the first measurement is 4,038, and at the second it is 4,192. This would amount to a semi-annual average increase of 154 cubic centimeters.

Table of lung capacities.

It remains to be added that the lung capacities were taken by means of a dry spirometer registering cubic inches, which, for the sake of uniformity, were afterwards converted into cubic centimeters. There is, perhaps, no single subject in connection with physical training upon which more stress should be laid than the necessity of developing the lung capacity. The capability of drawing a sufficient amount of oxygen into the system to supply at all times and under all conditions and circumstances the necessary quantity for the full performance of the functions of every living cell in that system must ever be looked upon as a condition of the utmost importance. It is one of the principal aims of the physical educator. On the other hand, the reserve materials, not being regularly oxidized, would gradually accumulate, and their presence in excess in the economy lead in the end to the most serious disturbances of health through auto-intoxication. Now, the quantity of air introduced into the system at each inspiration being, naturally, regulated by the capacity of the lungs, it is of great importance that the conditions under which muscular work is capable of increasing that capacity should be thoroughly understood. According to Lagrange, too much importance has been attached to the development of those of the muscles that elevate the ribs, and I am sure that the same mistaken idea prevails in this country with regard to the influence on chest capacity to be derived from the use of the popular chest weights.

According to the same author, Demény's conclusions to the effect that more air enters the chest in the attitudes in which the scapulæ are drawn back and fixed by the tonicity and contractions of the rhomboidii, trapezii, and latissimi dorsi muscles, the belly retracted by the aspiration of the viscera into the thorax, than during repose, are entirely wrong. In this condition we find that all the inspiratory muscles except the diaphragm are in a state of forced contraction; the diaphragm alone remains in the position of respiration, and yet this is exactly the condition in which we find ourselves in the so-called position of attention so much insisted upon by the instructors of infantry tactics. The truth of this matter is that whatever is gained in lung capacity by the elevation of the ribs is lost by the ascent of the diaphragm, and, therefore, as an exercise for increasing the lung capacity, the manœuvre is absolutely without value. A similar, if not identical, condition of things prevails during exercises on the various chest weights. If, on the other hand, we will take a very deep inspiration, we find that we are able not only to raise our ribs to the greatest possible limit, but we will also find that the diaphragm, which is the largest and most powerful inspiratory muscle, will share in the movement and will push the abdominal viscera downward, instead of allowing them to be sucked up into the chest, thus materially enlarging the chest capacity. The vertical diameter

I.—Influence of special exercise on lung capacity.

The table and chart show that at the end of one month an average increase of 331 cubic centimeters or 20 cubic inches was observed, which amount is twice that observed in the 50 cadets at the end of six months' gymnastic work. During running most all of the muscles of the human body are actively engaged, some more, some less; a large amount of venous blood is poured into the right side of the heart and through the lungs; an immense thirst for oxygen causes the deepest inspiration which, often repeated as they are, must give rise to an increased lung capacity, providing we do not at the same time take too heavy exercises, engaging the muscles that cover and surround the chest, thus tending to compress it from without. It was said above that besides running a large amount of muscular work, *done within a short space of time*, was one of the means of increasing the lung capacity. With regard to this point, I thought it interesting to ascertain what influence on the lung capacity of the players was provided by the popular game of football. The football season at Annapolis begins after October 1, and on October 15 I examined 17 players who were the most likely to continue playing throughout the season with regard to their lung capacities. The same players were examined on November 21, and I must confess my surprise was great when they nearly all came back with the same lung capacities. The only increase in lung capacity that had taken place was noted in two half-backs, just the ones who had to do most of the running. Whether the results of my observations would have been different if I had been able to make my first examination on October 1 instead of the 15th, or not, I am, of course, unable to say; but these observations have gone far to convince me of the fact that if there is any influence in football playing on the lung capacities of the players, that influence must be exerted early in the beginning of the period of training, for after the chest is loaded down with strong, hard muscles, it must become almost impossible for the chest capacity to enlarge to any perceptible extent.

Now, while from a physiological point of view it is perfectly possible and intelligible by the proper exercise to increase the respiratory efficiency of a certain limited area of lung surface without even increasing the capacity of the lung itself, it might, nevertheless, be deemed good advice to attend to the lung capacity according to the best principles before attempting to play the game of football in real earnest. At any rate, as long as the exchange of gases in the lung is simply a physical process, depending upon the difference in partial pressure between the  $\text{CO}_2$  contained in the blood on one side of the respiratory mucous membrane and the O of the inhaled air on the other side of this same membrane, the amount of O taken in, and of  $\text{CO}_2$  given out, must be looked upon as being in direct proportion to the lobal capacity of the lung as ascertained by the spirometer.

#### TOTAL STRENGTH.

For the purpose of ascertaining and noting any changes that may have taken place in any individual human being after having had a course of physical training in the gymnasium or elsewhere, it is absolutely necessary that we should have several very thorough tests and established standards of sufficient scientific accuracy easily applied and uniformly accepted and followed, by means of which progress in certain directions can be definitely ascertained and the results compared. Among those that have so far been recommended the total strength test is a most valuable one. When I first began to work with it I must confess I had little confidence in its value, but further experience with it has caused me to look upon it as a most important and significant index. It was for the purpose of still further testing the value of this index that the 50 cadets in question were divided in accordance with the amount of increase in total strength that had taken place during their six months' training in the gymnasium. On looking at the table indicating their total strength, I took 100 kilos as the dividing line, placing those whose increase was less than that on one side, and those whose increase exceeded that limit on the other, and found that they were quite equally distributed, namely, 25 on either side; and,

so far as we have gone, we have found the average height, weight, and lung capacity much in favor of those whose increase in total strength was above 100 kilos, a very significant factor, even if the number of individuals under observation here is not over large. Physiological truths do not require in all cases an overwhelmingly large number of individuals to establish them by, but a smaller number will suffice for them than would suffice for the establishment of the average length of the human femur or the thickness of the thigh.

How is this total strength of an individual calculated? The exact amount of work done by our muscles in complicated cases of labor is by no means easily determined and, in fact, has not been determined except in a few special cases. It is well known that during muscular work of any kind, according to the laws of nature, certain substances are used up, the quantity of which must be subject to calculation from the amount of work that was done, for the law of conservation of energy holds true in the organic as well as in the inorganic world. The amount of work done in these cases is generally expressed in kilogrammeters, 1 kilogrammeter indicating the amount of work necessary to lift 1 kilogram to the height of 1 meter, or 1 gram to the height of 1,000 meters, etc. Thus, the amount of work performed in walking is usually calculated, according to Rubner, by the following formula:  $0.071 \times k \times p$ , in which formula 0.071 is the product of the height of lift and fall in each step,  $k$ , the body weight, and  $p$ , the number of steps taken. From the amount of work thus attained it is, on the other hand, easily calculated how much of albumin, carbohydrate, or fat was used up, because the caloric equivalent of work has been found to be 425 kilogrammeters for one calorie, and the number of calories produced by burning certain definite quantities of these substances being also known. But this method, although much more accurate and scientific, merely tells us the amount of energy that is necessary to be expended in certain kinds of special exercise or work, which, furthermore, may be distributed over a longer or shorter space of time. In making serial observations on a large number of individuals we wish more particularly to ascertain what is the total amount of available energy or strength which any of them may bring to bear upon an obstacle to be overcome at any given moment, and to calculate that a more rough and ready method had to be devised and adopted, and this method is the following:

According to the Anthropometric Manual of Amherst College, published in 1889, by Drs. E. Hitchcock and H. H. Seelye, the tests to be taken of an individual whose total strength is to be calculated are as follows:

1. *Expiratory strength*.—The subject, after loosening the clothing about the chest and filling the lungs, should blow with one blast into the manometer, an instrument made to register the expiratory pressure in kilos and tenths of kilos. Care should be taken that no air escape at the sides of the mouth, and that in expelling the air all the muscles of expiration are brought into play.

2. *Strength of back*.—The subject standing on the iron foot-rest, with the dynamometer so arranged that when grasping the handle with both hands his body will be inclined forward at an angle of 60 degrees, should take a full breath and without bending the knees give one hard lift, mostly with the back. (See Fig. 1.)

3. *Strength of legs*.—The subject while standing on the foot-rest, with body and head erect, and chest thrown forward, should sink down by bending the knees until the handle grasped rests against the thighs, then taking a full breath he should lift hard, principally with his legs, using the hands to keep the handle in place over the thighs. (See Fig. 2.)

4. *Strength of upper arms; triceps*.—The subject while holding the position of rest upon the parallel bars, supporting his weight with arms straight, should let the body down until the chin is level with the bars, and then push it up again until the arms are fully extended. Note the number of times that he can lift himself in this manner.

Fig. 1.

Fig. 2.

Fig. 3.

5. *Strength of upper arms; biceps.*—The subject should grasp a horizontal bar or pair of rings and hang with the feet clear from the floor while the arms are extended. Note the number of times that he can haul the body up until his chin touches the bar or rings.

6. *Strength of forearms.*—The subject, while holding the dynamometer (Fig. 3) so that the dial is turned inwards should squeeze the spring as hard as possible, first with the right and then with the left hand. The number of kilos may be read off from the dial and noted.

*Total strength.*—From the above data the total individual strength is calculated as follows: The bodily weight is multiplied by the sum of the dip and pull; this is divided by 10 to prevent too large a number of figures in the calculation. To this is added the strength of back, the strength of legs, the average of the forearm, and the lung strength, and the result is looked upon as the total strength. For example, the weight of the subject being 64, the dip 11 and the pull 12 = 23; the back strength 150, and the leg strength 180; the forearm strength 45, and the lungs 2.0, the result will be:  $64 \times 23 \div 10 + 150 + 180 + 45 + 2 = 524$ . Just why the strength of the muscles of the upper part of the body was not originally included in this test is now difficult to make out. The strength of both the chest muscles and those that extend between the spinous processes and the shoulder plate can easily be ascertained by one and the same instrument. These are actually given in the New Manual for Physical Measurements, by Dr. Luther Gulick, whose excellently illustrated manual should be in the hands of everyone taking such measurements.

For the sake of uniformity of records we have, however, adhered to the original formula and our tables have all been calculated in accordance with it, so as to make them comparable with those ascertained by all who are taking such tests elsewhere. This strength test is not devoid of all scientific accuracy, but possesses a certain definite physiological value. If we take, for instance, the gastrocnemius of a frog and pass an induction shock through it, we get a contraction, whether we stimulate directly or indirectly. If we attach certain weights to one end of the muscle and increase them gradually and stimulate, there comes a time when our stimulus is no longer answered by a contraction of the muscle and the weight attached to it will no longer be lifted, although the stimulus passes through the muscle as is indicated by the galvanometer. In this condition, in other words, we have arrived at the weight which exactly counterbalances the absolute power of the muscle under observation. In the above-described strength test we have, undoubtedly, an analogous condition of things. The number of kilos which we can lift with our backs and legs being the exact amount necessary to counterbalance the strength of those muscles that were engaged in pulling, in other words indicating their absolute strength just the same as the absolute power is represented by weight in the experiment with the frog's gastrocnemius.

The muscular contraction produced by the stimulus of the will may perhaps not be a maximal contraction and the curve produced in the case may not be anything like the curve produced by a single induction shock, but resemble more nearly a tetanic curve, still the amount of strength that these tests require us to exert at the time represents the greatest possible amount which we are capable of exerting at any one time and which is here expressed in kilos just the same as the absolute power is represented in weight in the experiment with the frog's gastrocnemius.

Total strength table.

| 14 ..... | 16 | 5  | 304 | 520 | 216 |           |    |    |     |     |     |

On examining the two total strength tables we find that they average up as follows: The 50 cadets on their entrance examination developed an average total strength of 385 kilos, and at their second examination, or about six months later, the average total strength was 508½, showing a gain of 123½ kilos, which is the highest average gain ever noted at the Academy between the first and second examinations. Furthermore, when we compare their average strength with that of Amherst students of the same age, we find that the cadets on entering were 35 kilos behind the Amherst students, whose average strength at 18 years, and which is our average age, is given by Hitchcock as 420 kilos; but after the second examination and comparing its results with those obtained from the same students, even at 19 years of age, we find that the cadets are 50 kilos ahead of the Amherst students, whose average strength at that age is given as 448 kilos, while that of the cadets is 508½ kilos, which is about 20 per cent above the average total strength obtained from 2,230 of the Amherst students.

Looking at Table A, and comparing the average with those of Table B, we find that the average increase of the first 25 is 77 kilos, while that of the second 25 is 170 kilos, although the former were 10 kilos ahead of the later at the first examination. In order to increase one's total strength, however, especially while young and still in the growing period of life, we do not always require very many months to do it in. A month or six weeks of well-directed exercise may add on from 25 to 30 per cent of that strength as is well shown in Table No. IV and Plate II.

II.—Influence of one month's special exercise on total strength of 18 cadets during spring of 1892.

III.—Influence of one month's practice at football on strength of 17 players.

TABLE IV.—*Influence of one month's special exercise on total strength of 18 cadets.*

[Average age, 19 years 3 months; average height, 1,721 mm.; observation made in April, 1892.]

\* Sickness.

Table IV presents the same cadets as regards total strength as Table III and Plate I of the lung capacity, the two observations being made, in other words, on the same cadets at the same time. We see that after such a short time as one month's specially directed exercise, which was very light at that, and beginning with an average of 524 kilos, we had obtained an average increase of 112 kilos=636 kilos. Still more apparent does that become on Table V and Plate III. Here, although the average increase does amount only to 105 kilos, it must be remembered that the initial average strength of the seventeen cadets measured was 644 kilos, and at the end of 5 weeks foot-ball practice it amounted to 747, with a maximum of 974 and a minimum of 612. Assuming, as we must, that there exists a natural individual limit to development in strength, the increase must become slower the nearer we approach that limit, just the same as growth in height becomes slower from year to year as we approach the final limit of our intended height.

TABLE V.—*Influence of one month's practice at football on total strength of 17 players.*

## VITAL CAPACITY.

The term "vital capacity" as employed in connection with the usual anthropometric records appears to me somewhat misleading, inasmuch as it implies in its meaning a certain physiological significance which it does not possess. The name "vital capacity" was originally used by Hutchinson to denote the respiratory capacity of an individual, and which is usually measured by a modified gasometer (spirometer of Hutchinson), into which the subject breathes, making the most prolonged expiration possible after the deepest possible inspiration. The quantity of air which is

thus expelled from the lungs is indicated by the height to which the air chamber of the spirometer rises, and by means of a scale placed in connection with this the number of cubic centimeters is read off.

The vital capacity as recorded on anthropometric charts in use in our gymnasiums is obtained by different methods, namely:

(1) Seaver (Anthropometry) arrives at it by multiplying the length of trunk, depth of chest, and breadth of chest together; the result is the vital capacity. (2) Gulick (Manual for Physical Measurements) states that the vital capacity refers to the size of the trunk, but "does not represent the cubical size of the body, although it varies in a general way with it." He calculates it by multiplying the length of the trunk by the average between the depth of the chest and the depth of the abdomen, this again being multiplied by the average between the width of the chest and the width of the waist. Just what this so-called vital capacity is intended to represent does not appear to be very clearly defined in the descriptions of the methods for obtaining it. If, as Dr. Gulick states, it does not represent the cubical size of the body, what does it represent? It certainly appears to have little, if any, definite physiological significance so far as a man's chances for life are concerned, for these can simply not be measured in this manner, and if not, why should we continue to apply the term "vital capacity" to what is in reality nothing but the capacity of the trunk?

In the adjoining two tables of the vital capacities, calculated according to Gulick's method, it will be noticed that the losses on both exceed the gains, and we now must ask ourselves how this result has come about. Let us take the example of a boy 18 years of age just entering college and taking a course in the gymnasium for the first time in his life. He is measured in the usual manner, presents a well-developed chest, padded with a goodly layer of adipose tissue, and a well-rounded abdomen. At the end of the academic year and after working well in the gymnasium he is measured again and it is found that he has grown taller, weighs more, is very considerably stronger, and has a greater lung capacity than the year before; but his adipose tissue has almost entirely disappeared and his abdominal walls have become more muscular. Consequently, his abdomen being less rotund; having, furthermore, also increased the strength of his respiratory muscles, he is able to contract his chest better, and the result of both these changes will be that he has lost in vital capacity, much to his chagrin, and it certainly would be most disheartening for him to be told that he had grown taller, heavier, and stronger at the expense of his vital capacity. On the other hand, a man at 40 years of age, the age when in most persons the stomach obtains its final triumph over the chest and permanently establishes its supremacy over the latter, so far as prominence is concerned, will, on being similarly measured, give a greater vital capacity than he did at the age of 25 or 30 years of age, when, perhaps, his physical condition was at its best and his chances for life greatest. I should, accordingly, propose the term "capacity of the trunk" in place of "vital capacity," as ascertained by the methods above detailed. The average vital capacity of the 50 cadets at the first measurement, as shown by these tables, was 3,152 cubic centimeters, and on the second measurement it was 3,085 cubic centimeters, or 67 cubic centimeters less. Since the anthropometric tables so far published by either Hitchcock, of Amherst, or Seaver, of Yale, do not include the vital capacity, it is, of course, impossible to make a comparison.

Table of vital capacities.

## VITAL INDEX.

Under the above name, Enebuske has introduced the ratio of lung capacity and weight of Demény. This index appears to me to be of considerable physiological significance in connection with the subject of physical training and the study of its results. From the physiological, point of view the introduction into scientific physical training of valuable and significant indexes, such as the above, is as much of a necessity and of as great importance now as was the introduction of weights and measures into chemistry a hundred years ago.

The original papers of Demény are not accessible to me, but Dr. Enebuske states that Demény has found that in children of the same age the lung capacity is proportional to their weight, and that if a curve is constructed of lung capacity and weight in function of age, the two curves are parallel. Demény has furthermore found that the ratio of lung capacity and weight of persons who have undergone a course of systematic physical training is much higher than in persons who have had no such training, from the fact, familiar to us all, that the training on the one hand increases the lung capacity, and on the other diminishes, at least in the beginning, the weight by causing a great quantity of the reserve tissue (fat) to disappear.

In the adjoining two tables of vital indices I have applied this index to the 50 cadets under observation. It will be noticed, however, that but 16 out of 50 have gained, 31 have lost, and 3 have remained the same. The average vital index obtained from both tables together at the first examination was 0.0679, at the second examination 0.0667, amounting to an average loss of 0.0012.

It will furthermore be noticed that for the first time, so far as we have gone in our comparative study of these two tables, the first table presents higher averages than the second table. It was found, in other words, that the 25 cadets whose increase in total strength was 100 or more kilos, and who are always represented by Table B, were taller, heavier, stronger, and had a greater average lung capacity than the 25 whose increase in total strength had been found to be less than 100 kilos, and who are always represented by Table A. In the tables of the vital indices we meet with the first exception to this. An average decrease in vital index of 0.0012 may not be very great, but it is certainly appreciable, and must have a cause, for I firmly believe in the validity and significance of this index. On referring back to the tables of the lung capacities and taking Table B, it will be noticed that, besides the average increase being smaller than in Table A, 5 out of the 25 have remained the same and 3 have actually lost in lung capacity. No matter how disheartening it may be to realize such results, the finding them out is as important and salutary as the obtaining of contrary results would be gratifying.

Table of vital indices.

I have for some little time past been dissatisfied with the progress that the cadets have made in breathing capacity consequently this last year, in superintending the exercises, special stress was laid on the importance of breathing exercises on chest weights and special attention was paid to carefully graded running, and I am as firmly convinced that the instruction and drill which the cadets have received in the gymnasium was as well calculated to develop their lung capacities as any that could be devised as I am that the vital index is true and not misleading. What, then, is the cause of the decrease in vital index? I believe it due to the snug-fitting

uniforms in which cadets of this school are done up and which they are obliged to wear the greater part of the day. Although this seems to me quite a reasonable explanation, this fact can only be established by the study of and comparison with the statistics of other military schools. When, however, we compare our average of vital index of the 50 cadets, obtained at the second examination, and which is 0.0667, and find that it is above the average of the 50 per cent Yale student and only below the average vitality of 113 Swedish navy recruits (aged 19), we have, as yet, no great cause for being alarmed, but are, on the contrary, very much encouraged. It is furthermore obvious that any increase in weight, from no matter what cause, may in a few instances cause considerable lowering of the Vi. This would make it appear certain that a high Vi. would be in most cases a sure indication of perfect training, whether it is noticed in children, women, or men. In a large number of scholars doing a certain amount of exercise, especially after the first few months, I have frequently noticed quite considerable increase in weight as a direct result of the exercise, and, as will be noticed on referring to the tables of weights, this average increase in the cases of the 50 cadets is over 3 kilos. Even admitting that a man in perfect training must have a high Vi., the object is not invariably attained in all cases, and more often requires special attention and training.

Our average is higher than that given by Demény of methodically trained Frenchmen aged 22, and which is 0.0615.

As regards the meaning of this index, Dr. Enebuske says:

If we were compelled to translate this index into popular language, we could not come nearer the truth than to say that it means power of resistance during the emergencies of disease,\* and that it expresses an essential and fundamental condition for endurance under effort. It does not represent the moral or nerve-dynamic elements of endurance, but it represents a chemico-dynamic component of endurance.

Demény (quoted by Enebuske) makes this statement:

By taking young gymnasts and arranging them according to the decreasing value of their rates of lung capacity and weight, we have been able to ascertain that thereby we have made a classification that corresponds sensibly to their degree of resistance.

In practicing gymnastics Enebuske has observed a marked correspondence between the vital index and ability in such exercises in which the weight of the body is carried by the arms or thrown from the ground by forcible contractions of the muscles of the legs, as jumping and vaulting. Taking perpendicular rope climbing as an example, he found that 6 out of the 26 students examined by him could not climb the rope and that their Vi. was below 0.0478; the remaining 20, whose Vi. was above 0.0478, could all climb except one.

Owing to the fact that the publication of Dr. Enebuske's paper was much delayed, I regret that I was unable this year to test his conclusions in this direction, but this much is certain, namely, that for endurance there is nothing more essential from a physiological point of view than a large lung capacity.

#### THE POWER INDEX.

This index is the Vi. multiplied by the total strength of the individual. The average power index of the 50 cadets at the first examination was 26.23, and at the second examination it had increased to 33.38, making a difference of 7.15 between

---

\* As to whether we are entitled to this assertion or not, experience in other directions than that of mere gymnastics must prove how this could be brought into harmony with our present understanding of infectious diseases. Comparisons must be made at the bedside. I know of at least one instance which would not bear out this assertion. A gentleman prominent in football, in excellent condition, whom I measured only three weeks before his death, and whose vital index was 0.0782, died of typhoid fever in the surprisingly short time of a week.

the two examinations. Looking over the Amherst table of the 50 per cent student and calculating from the data given there the power index we get a power index of 28.5843 for the average Amherst student.

(See the adjoining two tables of the power indices.)

STRENGTH-WEIGHT INDEX AND VITAL-STRENGTH-WEIGHT INDEX.

For the sake of future reference and comparison I append also the tables of these two indices. The strength-weight index is expressed by the formula  $\frac{T.S.}{W.}$ , and the vital-strength-weight index by that of Vi.  $\frac{T.S.}{W.}$  The results are recorded in the tables.

**HEART RATE.**

The association gymnasium record blanks direct that the heart rate should be ascertained before and immediately after the strength tests. Experience has shown that a weak heart beats fast very readily, even on slight exertion, while a strong one does not do so. The principle is perhaps best illustrated by the following table, which belongs to an officer 28 years of age, and who for about a year devoted himself most conscientiously to systematic training:

| Number of examination. | July 4. | Oct. 7. | Dec. 16. | Jan. 4. | May 3. |
|------------------------|---------|---------|----------|---------|--------|
| Pulse (1) .....        | 100     | 92      | 88       | 88      | 72     |
| Dip .....              | 1       | 3       | 6        | 13      | 14     |
| Pull .....             | 5       | 11      | 12       | 13      | 12     |
| Back .....             | 155     | 150     | 170      | 200     | 180    |
| Legs .....             | 280     | 310     | 320      | 270     | 325    |
| Forearm .....          | 35      | 45      | 43       | 46      | 40     |
| Strength of lung ..... | 25      | 25      | 25       | 26      | 20     |
| Weight .....           | 66.5    | 61.5    | 62.5     | 64      | 61.5   |
| Pulse (2) .....        | 160     | 134     | 120      | 104     | 110    |
| Total strength .....   | 511     | 593     | 647      | 686     | 714    |

In this diagram we notice a steady decrease in the number of heart beats, not only as regards the initial pulse rate (pulse 1), but also in the rate recorded after the strength test had been taken. This is as it should be.

There is, then, no doubt that a strong and vigorous heart is one of the results of systematized exercise, but this result is only attained not only by the greatest possible care and attention to details on the part of the director of such exercise, but it also requires the most conscientious coöperation on the part of the person taking the exercise. In my experience results like these are exceptional as occurring in pupils that are exercised in classes, and without their receiving individual and quite special care and attention. The more we study the subject of physical training the more also the individual differences and personal peculiarities of mankind become apparent. There are a number of qualities, no less real than those that we can weigh and measure, that are both imponderable as well as immeasurable.

In the 50 cadets under observation the greatest differences with regard to the pulse rate have been observed. Some present a greater initial pulse rate at their second examination than they did at their first examination, and in some even the pulse rate after taking the strength tests was higher at the second examination than it was at the first examination; in some no change has taken place, and in still others marked improvement has been recorded.

By practicing certain forms of exercises we no doubt become able to dominate over certain actions not ordinarily under the control of the will. We learn to regulate the working of our lungs, thus also influencing the heart rate; but it is almost impossible for any one, no matter how well trained he may be, to do his best at these strength tests without at the same time increasing his heart rate to some extent. Indeed, one of the first effects of exercise of any kind is to increase the frequency of the heart beat, as we all know, and consequently to quicken the blood current. No one has ever seen a person doing the "dip" or the "pull" without noticing the pale skin over the working muscles become intensely red and congested looking, owing to the increased amount of blood that is flowing not only to the working muscles, but also to the periphery generally. On making so great an effort in so short a time as these strength tests require, one being taken right after the other, without rest during the intervals, and owing to the large amount of blood which is sent to the periphery in consequence it is, perhaps, quite natural to find the arterial pressure fall and the pulse rate quicken. I have myself not been able, owing to an absence of the proper instruments, to make accurate and conclusive experiments in regard to blood pressure, but the accompanying sphygmograms would go far to render the existence of a lowering of blood pressure after this strength test probable in a majority of cases. Nothing, however, short of accurate pressure tests will decide this most interesting point. Oertel (*Handbuch I, Therapie I, Kreislaufs störungen*), 1891, in a very painstaking series of experiments, has conclusively shown that the blood pressure rises somewhat on prolonged walking and mountain climbing, also that there is an increased pulse-rate. Both these changes in the circulation produced by this form of exercise persist for some time, even after the feeling of fatigue has quite passed away, which latter point has also been observed by Lagrange (*loc. cit.*). Our results, however, are not comparable to those of Oertel. The curves which we present were taken immediately after a severe effort was made, and before anything like a thorough equalization of venous and arterial circulation could have taken place. The fall in arterial pressure in a sudden effort may be due to the fact that more blood is suddenly thrown into the veins than is returned into the left side of the heart, and also to the incomplete oxygenation of the blood, which must have a depressing effect on the heart itself. Oertel's blood-pressure tests were made hours after the start, consequently long after the balance between venous and arterial circulation had been restored, and the exercise taking place in the open air, the blood after a long walk or climb was in a much improved condition, in so far as oxygenation is concerned, and hence the rise in blood pressure.

The accompanying diagram (IV) and Table VI, however, show that well-regulated exercise strengthens the heart so that it may resist, as it were, the sudden invasion of effort to a certain extent.

## THE GLOBULICIDAL ACTION OF BLOOD SERUM.

By WILLIAM S. CARTER, M. D.,

*Assistant Demonstrator of Pathological Histology, University of Pennsylvania.*

It is well known that if we inject into the veins of some animals the blood serum of certain other species of animals there results a hæmoglobinuria and albuminuria. The destruction of red corpuscles has also been observed under the microscope by mixing the blood serum with a drop of blood from another species. This was investigated twenty years ago by Landois\* in relation to transfusion. More recently it has been found that blood plasma instead of being simply an inert solution of globulins, albumins, extractives, and inorganic salts, whose chief functions it was to serve as a means of conveying the blood corpuscles to different parts of the body, is really a powerfully active fluid and performs a number of wonderful phenomena. It has been shown that in infectious diseases in which the bacteria are not found in the blood there are in solution in the serum certain products of bacterial metabolism. What seems more important, it has been pointed out by Mettalt† and by Buchner‡ and many others that the blood serum of animals refractive to certain diseases is highly destructive to the bacteria causing those diseases. This peculiar function has been called the germicidal or bactericidal action of blood serum and Buchner has shown that it is probably due to a globulin. These observations are very important and indicate that Metchnikoff's well-known theory of phagocytosis is not the only factor in the destruction of bacteria by the blood. The fact has further been established that animals naturally susceptible to certain diseases can be immunized to those diseases by the injection of the blood serum of animals either naturally immune or rendered immune artificially. Furthermore, even after infection has taken place the injection of blood serum of immune animals will promptly neutralize the poison and terminate the disease. This very important practical use of blood serum is certainly the most promising thing of modern medicine and the burning question of the day, for now we are able to cure infectious diseases, and apparently in the way nature cures them. Thanks to Belering, Kilasato, Cantani and Tizoni, and the Klemperers, we are now able to meet tetanus, pneumonia, and diphtheria and not feel that we can not modify the course of the disease.

\* Centralblatt für die Med. Wissenschaft., 1873, pp. 883, 897.

† Inaug. Diss., Göttingen, 1890.

‡ Centralbl. f. Bakt., Bd. V, S. 817, &amp; Bd. VI, S. 1.

With these facts before us, the destruction of blood corpuscles by a foreign serum has assumed a greater importance. Recently this property, which has been called the globulicidal action of blood serum, has been studied by Buchner\* and by Daremberg.† These observers have independently found that this property was destroyed by heating to 55 to 60° C. for some time, or by dialysis. Buchner further states that this property is lost by preserving the serum for some time outside the body. All these observations, together with those of Maragliano‡ on the globulicidal action of the blood serum in different pathological states, were made on the field of the microscope.

The experiments presented in this paper were made as follows:

The blood serum was obtained (except from man) by introducing, with antiseptic precautions, into the blood vessel a carefully sterilized long glass canula. By this means the blood was received directly into a sterilized glass flask. From man the blood was obtained from the arm after it had been carefully cleansed and washed with antiseptics. The blood was then set aside in the ice chest and allowed to clot. The clear serum was then injected either intravenously or subcutaneously into another animal, by means of a sterilized burette and canula. There was no bacterial contamination in the handling of the serum. The effect upon the blood of the animal thus injected was determined by means of the Thoma hæmocytometer, the diluting fluid being usually a 2.5 per-cent solution of bichromate of potash. The variation between different counts of the normal blood with this instrument is very slight, being on the average not over 200,000 or 300,000. The normal was obtained by counting the corpuscles twice before the injection. After the injection the counts were made as often as possible, or as often as seemed necessary. As each counting occupied considerable time, the condition of the blood could not be determined as often as desirable. The counting and diluting were always done by one person.

The experiments were made chiefly on dogs and rabbits, and the blood was obtained from these animals by sticking their shaved ears. Of course by manipulating the ear so much, the number of leucocytes must of necessity vary greatly, and so great is the variation between different observations in the normal state that unless there be a pronounced and constant change in their number, it can not be ascribed to the injection. In a few instances frogs were used, but it was found that the blood could only be obtained with such difficulty and the number of corpuscles varied so much, normally, from the admixture of lymph, that it did not seem desirable to continue experimentation in this direction.

Besides the numerical observations, it seemed also desirable to examine into the kinds of leucocytes. For this purpose cover-glass preparations were made, fixed, and then stained by eosin and hæmatoxylin. Five hundred leucocytes were counted at each observation and divided into the following classes: (a) Lymphocytes, (b) large mononuclear, (c) transitional, (d) eosinophiles, and (e) multinuclear.

#### HUMAN SERUM IN DOGS.

In three experiments in which the human serum was injected in large quantities into the veins of dogs there was no appreciable alteration in the number of the red or white blood corpuscles. Neither was there any alteration in the proportion of the different kinds of leucocytes which were examined in Experiment II.

*Experiment I (dog; weight, 52 pounds).*—12 M.: R. B. C., 6,550,000; W. B. C., 15,000. 12.30: R. B. C., 6,900,000; W. B. C., 31,000. 12.45 P. M.: Injected, per jugular vein, 125 c. c. human serum, 48 hours old, taken from an Italian, aged 48, with aneurism; no symptoms after injection. 2.30 P. M.: R. B. C., 6,800,000. 4.30 P. M.: R. B. C., 7,120,000; W. B. C., 54,000. 6 P. M.: R. B. C., 7,020,000; W. B. C., 37,000. Next day, 10 A. M.: R. B. C., 6,980,000; W. B. C., 25,000. 3 P. M.: R. B. C., 7,000,000.

\* Sitzungsberichte des Ärztlichen Verein, München, II, 1892.

† Arch. de Méd. Expér. et d'Anat. Path., Paris, 1891, Vol. III, 720.

‡ Berl. Klin. Woch., 1892, 765.

*Experiment II (dog; weight, 15 pounds).*—3 P. M.: R. B. C., 7,300,000; W. B. C., 20,000. 3.30 P. M.: R. B. C., 7,125,000; W. B. C., 20,000. 3.45 P. M.: Injected, per jugular vein, 100 c. c. human serum, same as in Experiment I; no symptom. 4.45: R. B. C., 7,700,000; W. B. C., 7,500. 6: R. B. C., 7,050,000; W. B. C., 7,500; urinated freely during night; albuminuria. Next day, 10 A. M.: R. B. C., 8,070,000; W. B. C., 40,000. 3 P. M.: R. B. C., 8,010,000; W. B. C., 45,000.

*Experiment III (dog; weight, 16.5 pounds).*—3 P. M.: R. B. C., 4,400,000; W. B. C., 10,000. 3.30 P. M.: R. B. C., 4,375,000; W. B. C., 6,250. 4.35: Injected, per jugular, 125 c. c. human serum, 6 hours old, from healthy young man, aged 20. 5 P. M.: R. B. C., 4,200,000. 5.45: R. B. C., 4,700,000. Next day: R. B. C., 4,675,000.

Normal: Lymphocytes, 7 per-cent; large mononuclear, 1 per-cent; transitional, 2.5 per-cent; multinuclear, 89.5 per-cent.

Two and one-quarter hours after injection of 125 c. c. human serum, 6 P. M.: Lymphocytes, 9.5 per-cent; large mononuclear, 2 per-cent; transitional, 4.5 per-cent; multinuclear, 84 per-cent.

In one experiment (II) albuminuria was observed. The urine did not show any hæmoglobin by Tinct. guiac and peroxide of hydrogen. The kidneys were cut in this experiment and on microscopic examination show the uriniferous tubules filled with granular matter, the outline of the cells showing indistinctly, while the nuclei still take the stain. In order to see if human serum had any toxic effect on dogs, a blood pressure experiment was made in which 100 c. c. of serum from a healthy young man was used. Immediately after the injection there was a slight lowering of pressure, followed by a marked rise to above the normal. The pulse and respiration were at first slowed but soon returned to normal.

From these experiments it would seem that human serum has neither a toxic or globulicidal action upon dogs.

#### HUMAN SERUM IN RABBITS.

*Experiment IV (small rabbit).*—1 P. M.: R. B. C., 4,750,000; W. B. C., 9,250. 2 P. M.: R. B. C., 4,200,000; W. B. C., 7,750. 3.14 to 3.25: Injected, per vein, very slowly 12 c. c. serum from man with aneurism, æt., 51. 3.26 P. M.: R. B. C., 3,062,000. 3.30 to 3.45: 12 c. c., injected very slowly. 3.50: Paraplegic. 4: R. B. C., 1,070,000. 4.10: Comatose. 4.20: Died in convulsion.

*Experiment V (large rabbit).*—3 P. M.: R. B. C., 6,850,000. 5.33: 12 c. c., human serum twenty-four hours old, rapidly. 5.40: Paraplegic. 5.42: General convulsion. 5.42: R. B. C., 2,900,000. 5.43: Died in convulsion.

*Experiment VI (large rabbit).*—2.30 P. M.: R. B. C., 5,510,000. 3.10 to 3.16: Injected per jugular vein, 19 c. c. serum forty-eight hours old, from young man. 3.16: R. B. C., 2,025,000. 3.16: Died of cardiac failure; no convulsion.

*Experiment VII.*—11 A. M.: R. B. C., 4,475,000; W. B. C., 6,250. 11.30: R. B. C., 4,680,000; W. B. C., 17,000. 12.27 to 12.31: Injected rapidly, 5 c. c. serum twenty-four hours old; man with aneurism. 12.35: R. B. C., 2,150,000; W. B. C., 25,000. 12.35: Died, heart failure; R. V. distended; no antemortem clot.

*Experiment VIII (medium-sized rabbit).*—3 P. M., R. B. C., 5,250,000; W. B. C., 6,000. 3.30 P. M.: R. B. C., 5,000,000; W. B. C., 7,500. 4.10: Injected slowly per jugular vein, 3 c. c. serum twenty-six hours old, from young man. 5 P. M.: R. B. C., 3,875,000. 5.25: Injected 6 c. c. slowly. 5.30: R. B. C., 3,500,000. Does not seem sick. Next day: Seemed very sick; incoördinate movements; did not seem to have control of posterior extremities; R. B. C., 3,000,000; killed.

*Experiment VIII (medium-sized rabbit).*—4 P. M.: R. B. C., 5,000,000; W. B. C., 6,250. 4.30 P. M.: R. B. C., 5,275,000. 5 P. M.: Injected slowly per jugular vein, 3 c. c. serum two days old, from young man. 5.05: R. B. C., 3,375,000. 5.10 to 5.12: 3 c. c. 5.20: 3 c. c. 5.25: R. B. C., 2,400,000. 5.30: 4 c. c. Slowly. 5.35: Slight convulsion; respiration labored; R. B. C., 1,450,000; died.

*Experiment IX (rabbit).*—A. M.: R. B. C., 6,925,000; W. B. C., 10,000. 8.30: R. B. C., 6,100,000; W. B. C., 40,000. 10 A. M.: Injected per jugular vein, 3 c. c. serum seven days old, from young man, aged 31. 10.30: Breathing rapidly. 10.50: Purging, lying on side. 10.56: R. B. C., 3,075,000. 10.57: Convulsion. 11: Died.

*Experiment X.*—8 A. M.: R. B. C., 6,650,000. 8.30: R. B. C., 6,500,000; W. B. C., 6,250. 9.30 to 9.35: Injected per jugular 10 c. c. human serum, eight days old, heated up to 55° C. for a moment. 9.45: R. B. C., 3,550,000. 10.10: R. B. C., 3,570,000. 10.30: R. B. C., 4,150,000; W. B. C., 10,000. 10.58: Slight convulsion. 11: Died in convulsion; heart beating on opening chest; right ventricle distended with dark blood, which shows R. B. C., 4,740,000.

*Experiment XI (large rabbit).*—12 M.: R. B. C., 6,825,000; W. B. C., 5,000. 12.30 P. M.: R. B. C., 6,000,000; W. B. C., 9,250. 2.08: 15 c. c. human serum eight days

old, heated to 56° C. for five minutes. 2.20: R. B. C., 4,900,000; W. B. C., 3,000. 2.40: R. B. C., 5,400,000; W. B. C., 3,100. 3: R. B. C., 5,125,000; W. B. C., 9,000. 4.30: R. B. C., 5,275,000; W. B. C., 12,000. No symptoms; complete recovery.

*Experiment XII.*—9 A. M.: R. B. C., 7,120,000; W. B. C., 7,700. 9.30: R. B. C., 7,025,000; W. B. C., 7,500. 3 P. M.: R. B. C., 7,450,000; W. B. C., 5,000. 3.15: Injected 25 c. c. human serum four days old, from man with aneurism. 4.15: R. B. C., 6,570,000; W. B. C., 6,250. 5.30: R. B. C., 6,950,000; W. B. C., 4,800. 6 P. M.: Urine contained albumin. 6.30: R. B. C., 6,500,000; W. B. C., 13,000. 8: R., 5,400,000; W., 4,700. 9.30: R. B. C., 5,540,000; W. B. C., 7,700. 12, midnight: R., 5,550,000. Next day, 8 A. M.: R., 5,975,000.

*Experiment XIII.*—12 M.: R. B. C., 6,000,000; W. B. C., 20,000. 12.30: R. B. C., 6,300,000. 1 P. M.: 20 c. c. human serum, eighteen hours old, subcutaneously. 4 P. M.: R. B. C., 6,800,000. 6 P. M.: R. B. C., 6,450,000. Tumor at seat of injection same size as at 2 P. M. Next day, 11 A. M.: R. B. C., 7,350,000. 4 P. M.: R. B. C., 6,000,000.

From these ten experiments it is seen that when human serum is injected slowly into the veins of rabbits the red blood corpuscles are destroyed rapidly, sinking from 5,000,000 or 6,000,000 to 1,000,000, or to one-fifth their number. This destruction occurs within one hour from the time of the injection and during this time the animal usually has several convulsions, frequently dying in one. Palsies sometimes appear—usually a paraplegia. The pupils are dilated and there is a peculiar exophthalmos just at death. The respiration is at first slowed and then becomes labored and the animal usually dies of respiratory failure. When the injection has been rapid death comes on in a few minutes. In these cases there is a rapid destruction of the red blood corpuscles, but never to such an extent as if the injection had been made slowly. The number of corpuscles in these experiments were never reduced below one-half their normal number. In these cases the convulsions are often absent. The disturbance of respiration and the exophthalmos are also present here but the animal dies of cardiac failure.

Recovery has taken place after the injection per vein of 9 c. c. slowly, with the corpuscles reduced to one-half their normal, while on the other hand death has taken place after the exhibition of 3 c. c. of serum several days old, the destruction of corpuscles being very little greater in the latter case than in the former.

With subcutaneous injections there is a very slow absorption and the destruction is very slight and comes on late. There are no toxic symptoms from the use of 25 c. c. in this way. The globulicidal action of human serum was not lost after the serum had been standing seven days, in Experiment IX. In fact, it seemed more toxic, probably on account of some putrefactive process, although there was no bacterial contamination. Momentary heating of blood serum to 55° C. does not lessen the toxicity or destroy the globulicidal action, but when heated for some minutes the blood serum had no effect. There does not seem to be any great change in the number of leucocytes. When there is a great destruction of red blood corpuscles there is also a paucity of leucocytes. There is a slight alteration in the number of lymphocytes when the corpuscles are destroyed. In Experiment IV there was a slight increase in the number of lymphocytes, while there is a corresponding decrease in the number of the multinuclear form, while in VI½ there was no alteration.

*Experiment IV.*

[Kinds leucocytes.]

Albuminuria was present after the subcutaneous injection, but no hæmoglobinuria. In the other cases there was no opportunity of examining for the wind. The kidneys show a very marked structural change; the whole renal tubule seems filled with granular matter and even the nuclei do not take the stain. It is also interesting to note that in these experiments, in which a destruction of red blood corpuscles was taking place, there was a peculiar grouping of those cells and in the field one can see many corpuscles which have lost their color and are very indistinct. In the fixed preparations made for examining the leucocytes, the red blood corpuscles stain very poorly with eosin when they are being destroyed.

## HUMAN SERUM IN FROGS.

*Experiment XIV (medium-sized frog).*—11 A. M.: R. B. C., 425,000. 12 M: R. B. C., 416,000. 1 P. M: Injected 5 c. c. human serum 3 days old subcutaneously. 7 P. M.: R. B. C., 200,000. 12 midnight: R. B. C., 232,000. Next day: R. B. C., 217,000; seems very sick.

*Experiment XV (large frog).*—3 P. M: R. B. C., 552,000. 4 P. M: R. B. C., 438,000. 5 P. M: 10 c. c. human serum 3 days old. 12 midnight: R. B. C., 310,000. Next day, 3 P. M: R. B. C., 320,000.

*Experiment XVI (medium-sized frog).*—10.30: R. B. C., 200,000. 11.30: 5 c. c. human serum heated to 55° C. 7 P. M: R. B. C., 260,000.

From this it would appear that human serum has a distinctly globulicidal action upon the corpuscles of a frog when injected subcutaneously.

## DOG'S SERUM IN RABBITS.

*Experiment XVII (big brown rabbit).*—12 M.: R. B. C., 5,260,000; W. B. C., 7,000. 3 P. M.: R. B. C., 4,970,000; W. B. C., 4,500. 3.48: 3 c. c., dog's serum 4 days old injected rapidly. 3.50: Breathing slowly. 3.55: Slight convulsion and died.

*Experiment XVIII (white rabbit).*—12 M.: R. B. C., 5,600,000; W. B. C., 12,500. 1.49: 1 c. c. dog's serum, 1 day old, injected in jugular vein. 2.10: 1 c. c. 2.20: 1 c. c. 2.25: R. B. C., 4,200,000; W. B. C., 12,000. 2.38: 2 c. c. 2.45: R. B. C., 4,680,000; W. B. C., 6,200. 3: 2 c. c. 3.05: R. B. C., 4,960,000; W. B. C., 6,250. 3.30: 6 c. c. slowly. 3.35: 2 c. c. 3.38: Died; slight convulsion.

*Experiment XIX.*—1.30: R. B. C., 5,066,000; W. B. C., 7,600. 2.29: 3 c. c. slowly injected into vein. From dog forty-eight hours before 2.42: R. B. C., 5,000,000; W. B. C., 4,000. 3.10 to 3.15: 3 c. c. 3.25: R. B. C., 5,083,000; W. B. C., 4,000. 3.48 to 4: 3 c. c. 4.05: R. B. C., 4,750,000; W. B. C., 3,000. 4.28 to 4.40: 4 c. c. 4.45: R. B. C., 4,880,000; W. B. C., 1,600. 4.55 to 5.38: 9 c. c. 5.40: R. B. C., 5,043,000; W. B. C., 2,100. 6: R. B. C., 4,428,000; W. B. C., 1,170. 6.10: Convulsion; respiration rapid. 6.17: Died in convulsion.

*Experiment XX.*—3 P. M.: R. B. C., 4,640,000; W. B. C., 12,000. 3.30: R. B. C., 4,400,000; W. B. C., 5,000. 4 to 4.45: 8 c. c. injected into vein, very slowly, dog's serum 4 days old. 4.50: R. B. C., 5,040,000; W. B. C., 10,000. 5.10: R. B. C., 4,800,000; W. B. C., 10,000. 5.15 to 5.40: 7 c. c. 5.40: R. B. C., 5,200,000; W. B. C., 11,000. 5.45 to 6.25: 13 c. c. 6.10: R. B. C., 5,400,000; W. B. C., 7,700. 6.27: 5 c. c. 6.30: R. B. C., 5,400,000; W. B. C., 12,500. Next day: R. B. C., 5,200,000; W. B. C., 9,375. Next day: R. B. C., 5,800,000.

*Experiment XXI.*—3 P. M.: R. B. C., 5,700,000; W. B. C., 5,600. 3.30: R. B. C., 6,022,000; W. B. C., 3,800. 3.52: 5 c. c., dog's serum, 1 day old, subcutaneously. 4 P. M.: 5 c. c. 4.15: R. B. C., 6,000,000. 4.45: 15 c. c., subcutaneously. 6: R. B. C.,

5,360,000; W. B. C., 8,600. 6.30: R. B. C., 6,100,000; W. B. C., 9,000. Next day: R. B. C., 4,460,000; W. B. C., 4,300; albuminuria and hæmoglobinuria. Next day: R. B. C., 4,170,000; W. B. C., 6,500; urine as yesterday. Next day: R. B. C., 4,690,000; W. B. C., 8,300.

*Experiment XXII.*—10.45: R. B. C., 6,400,000; W. B. C., 1,500. 12.30: R. B. C., 6,840,000; W. B. C., 11,000. 2.06: Injected 20 c. c. dog's serum, 4 days old, subcutaneously. 3: R. B. C., 7,500,000; W. B. C., 1,500. 4: R. B. C., 7,112,000; W. B. C., 10,000. 6 P. M.: R. B. C., 8,380,000; W. B. C., 6,200. Next day: R. B. C., 7,280,000; W. B. C., 7,000.

*Experiment XXIII.*—10.30: R. B. C., 6,010,000; W. B. C., 3,300. 12.30: R. B. C., 6,400,000; W. B. C., 6,000. 1.50: injected 15 c. c. dog's serum subcutaneously (several days old). 2.45: R. B. C., 6,030,000; W. B. C., 10,000. 4: R. B. C., 6,300,000; W. B. C., 18,000. 5.45: R. B. C., 6,200,000; W. B. C., 13,000. Next day: R. B. C., 6,100,000; W. B. C., 9,100.

*Experiment XXIV.*—2 P. M.: R. B. C., 5,630,000; W. B. C., 7,000. 2.30: R. B. C., 5,320,000; W. B. C., 7,600. 4.45: 25 c. c. dog's serum, 1 day old, subcutaneously. 9: R. B. C., 5,400,000; W. B. C., 7,800. 12: R. B. C., 5,500,000; W. B. C., 7,400. Next day, 6 A. M.: R. B. C., 5,400,000; W. B. C., 13,000. 9 A. M.: R. B. C., 5,960,000; W. B. C., 16,000. 12 noon: R. B. C., 5,400,000; W. B. C., 10,000. 7 P. M.: R. B. C., 5,060,000; W. B. C., 6,600. Next day: R. B. C., 5,500,000; W. B. C., 10,000.

*Experiment XXV.*—2.30: R. B. C., 6,500,000; W. B. C., 14,000. 5.15: 25 c. c. dog's serum, 1 day old, subcutaneously. 9 P. M.: 5,800,000; W. B. C., 9,500. 12 midnight: R. B. C., 6,800,000; W. B. C., 6,250. Next day, 7 A. M.: R. B. C., 6,520,000; W. B. C., 16,000. 12 noon: R. B. C., 5,800,000; W. B. C., 12,000. 7 P. M.: R. B. C., 6,800,000; W. B. C., 9,200. Next day: R. B. C., 6,400,000; W. B. C., 9,000.

With dog's serum, as with the serum of man, the rapid injection by the vein causes death in few minutes, often without convulsion. When the injection is made slowly, however, large quantities can be used, convulsions and death coming on late, or there may be entire recovery, even after 33 c. c. has been injected, as in Experiment XX. The toxic effect is not noticed until just before death, and is not as great as in rabbits injected with the serum of man. The globulicidal action is not very pronounced, the corpuscles never being reduced below four-fifths the normal quantity, and in several experiments there was scarcely any destruction. The diminution was no greater in the fatal cases than in those terminating in recovery. The white blood corpuscles did not undergo any decided numerical change, but there was a distinct alteration in the proportion of the different kinds. There was a distinct increase of the lymphocytes or the youngest leucocytes and a corresponding reduction of the multinuclear form, or the oldest leucocytes. By the subcutaneous injection there was in one case a decided diminution of red blood corpuscles to four-fifths their normal quantity, and at the same time albuminuria and hæmoglobinuria (Experiment XXI). The effect came on the day after the injection. I repeated this experiment four times, in apparently the same way, and even using larger quantities, but never obtained similar results; the only result of the injection in these cases was an albuminuria.

The kidney of the rabbit injected with serum from dog shows decided structural change, being similar to that resulting from the injection of serum of man, but not so severe. Ten c. c. of dog's serum one day old was injected subcutaneously in a frog, and the frog was found dead six hours later.

The results of injecting dog's serum into rabbits are different from those obtained by others in mixing dog's serum and rabbit blood. Landois, Buchner, and Daremberg all found dog's serum very destructive to the corpuscles of the rabbit. My experiments seem to warrant the conclusion that dog's serum is toxic, but much less so than the serum of man, and that it is scarcely at all globulicidal. The globulicidal action certainly could not explain the toxicity, for in the cases ending in death there was no greater destruction of corpuscles than in those ending in recovery.

*Varieties of leucocytes, dog's serum in rabbit.*

## HORSE'S SERUM IN RABBITS.

*Experiment XXVI (large rabbit).*—4.30: R. B. C., 5,742,000; W. B. C., 5,800. 5.30: R. B. C., 5,960,000; W. B. C., 6,500. 8.08 to 8.10: 12 c. c. horse serum 3 days old, injected per jugular vein. 8.10 to 8.18: 14 c. c., slowly. 8.30: R. B. C., 5,166,000; W. B. C., 31,500. 8.40 to 8.45: 10 c. c. 8.45 to 8.55: 15 c. c. 9 P. M.: R. B. C., 5,085,000; W. B. C., 8,200. 9.16 to 9.40: 25 c. c., slowly. 9.45: R. B. C., 4,810,000; W. B. C., 6,600; 6,600. 10.45: R. B. C., 4,910,000; W. B. C., 8,000. 12.30: R. B. C., 4,550,000; W. B. C., 27,000; urine contained albumin. Next day: R. B. C., 5,320,000; W. B. C., 9,800.

*Experiment XXVII.*—5 P. M.: R. B. C., 5,360,000; W. B. C., 9,375. 5.30: R. B. C., 5,600,000; W. B. C., 5,000. 5.55 to 6.19: 10 c. c. horse's serum 48 hours old, injected slowly per jugular vein. 6.20: R. B. C., 5,160,000; W. B. C., 11,000. 6.25 to 6.47: 17 c. c. 6.50: R. B. C., 4,720,000; W. B. C., 12,000. 6.55: 5 c. c. 7 to 7.30: 15 c. c., slowly. 7.30: R. B. C., 4,080,000; W. B. C., 7,500. 8.30: R. B. C., 4,200,000; W. B. C., 20,000. 9.30: R. B. C., 4,150,000; W. B. C., 10,000. 11.30: R. B. C., 4,825,000; W. B. C., 18,000. Next day: R. B. C., 4,125,000; W. B. C., 25,000.

*Experiment XXVIII (large rabbit).*—3 P. M.: R. B. C., 5,800,000; W. B. C., 5,250. 3.20: R. B. C., 5,700,000; W. B. C., 4,000. 5.45: Injection, subcutaneously 30 c. c. horse's serum 24 hours old. 8.15: R. B. C., 5,800,000; W. B. C., 6,700. 10.30: R. B. C., 5,820,000; W. B. C., 6,400. 1 A. M.: R. B. C., 5,720,000; W. B. C., 2,200. Next day, 10 A. M. R. B. C., 5,900,000; W. B. C., 10,000. 3 P. M.: R. B. C., 5,800,000; W. B. C., 5,000. 10 P. M.: R. B. C., 5,850,000; W. B. C., 8,500.

*Experiment XXIX (small rabbit).*—4 P. M.: R. B. C., 4,680,000; W. B. C., 7,500. 4.30: R. B. C., 4,960,000; W. B. C., 10,000. 5.15: Injection subcutaneously 20 c. c. horse's serum 1 day old. 8.15 P. M.: R. B. C., 4,680,000; W. B. C., 5,000. 10.30 P. M.: R. B. C., 5,240,000; W. B. C., 6,250. Next day, 1 A. M.: R. B. C., 5,080,000; W. B. C., 6,250. 10 A. M.: R. B. C., 6,040,000; W. B. C., 5,000. 3 P. M.: R. B. C., 5,600,000; W. B. C., 9,000; urine contained albumin.

From these experiments it will be seen that serum of the horse has no toxic effect upon rabbits. Although large quantities were injected directly into the veins of the rabbit (76 c. c. in one case and 47 c. c. in another), the number of corpuscles were not

reduced below four-fifths their normal quantity. It is probable that the dilution caused part of this reduction, for in the experiments in which horse serum was injected subcutaneously into rabbits there was no change in the number of corpuscles. There was no alteration in the number of leucocytes, but with intravenous injections there were fewer lymphocytes, while the multinuclear leucocytes were increased. With subcutaneous injections there was no alteration in the proportion. Albuminuria, but no hæmoglobinuria was produced.

Varieties of leucocytes, horse's serum injected into rabbits.

CAT'S SERUM IN RABBITS.

Experiment XXX (large rabbit).—3.30: R. B. C., 5,625,000. 4: R. B. C., 5,850,000; W. B. C., 7,500. 4.45 to 5: Injected 10 c. c. cat's serum one day old, per jugular vein. 5.15: R. B. C., 5,140,000. 5.35: R. B. C., 5,100,000. 6: R. B. C., 5,500,000; no symptoms.

In this one experiment in which 10 c. c. cat's serum was injected intravenously into a rabbit, there was neither toxic or globulicidal action.

SHEEP'S SERUM IN CATS.

Experiment XXXI (medium-size cat).—3.30: R. B. C., 5,200,000; W. B. C., 29,000. 4: R. B. C., 5,125,000. 4.05 to 4.10: Injected per jugular vein, 20 c. c. sheep's serum 1 day old. 4.15: R. B. C, 5,020,000; W. B. C., 11,000. 4.35: R. B. C., 4,500,000; W. B C., 12,000. 5: R. B. C., 5,000,000; W. B. C., 12,000. No symptoms; cat killed.

In this one experiment, in which 20 c. c. of sheep's blood was injected into the vein of a cat, there was neither toxic or globulicidal action.

To recapitulate. Human serum injected into veins of rabbits was found most toxic and most actively globulicidal. When injected rapidly it causes death in a few minutes, the corpuscles falling to one-half or one-third their normal number. When injected slowly death comes on much later, the number of corpuscles sinking to one-fifth the normal. In these latter experiments there were convulsions, paralysis, and great disturbance of respiration, and finally death by respiratory failure; but in the former, death came on rapidly by cardiac failure and without the toxic symptoms.

With dogs, human serum has neither a toxic or globulicidal action.

With frogs, human serum is both toxic and globulicidal.

Dog's serum is toxic when injected rapidly into vein of rabbits. When injected slowly in some cases death comes on with slight diminution of red blood corpuscles while in others recovery occurs, even after as much as 30 c. c. has been injected, with but slight reduction in the number of corpuscles.

With frogs, dog's serum is toxic.

The serum from the horse is neither toxic or globulicidal to rabbits.

Cat's serum in rabbits is neither toxic or globulicidal.

Sheep's serum injected into the cat is neither toxic or globulicidal.

Heat destroys both the toxic and globulicidal action of human serum. Standing in a cool place for seven days did not cause the serum to lose its globulicidal action; but the toxicity was increased.

There was no constant alteration in the number of white blood corpuscles, but when the red corpuscles are destroyed there is also a paucity of leucocytes. When human serum or dog's serum was injected into rabbits, the number of lymphocytes was increased while the proportion of multinuclear leucocytes was decreased. Horse's serum injected into rabbits increases the multinuclear leucocytes and diminishes the lymphocytes.

From the fact that the serum of the dog injected into rabbits is toxic without having any globulicidal effect and also from the fact that human serum injected rapidly into the veins of rabbits causes death in a few minutes, before the corpuscles are reduced below one-third their normal, while the slow injection causes a reduction to one-fifth their normal before death, it seems probable that the toxicity of serum is not dependent upon its globulicidal action and rather indicates a multiplicity of poisonous substances in the serum. The fact that heating destroys both the toxic and globulicidal action shows their albuminous nature. Buchner has also found that diluting the serum with water causes the globulicidal action to disappear, but it reappears on the addition of sodium chloride. Maragliano\* has found that in a number of diseases in man, in which the blood is altered, the globulicidal action is greatly increased, destroying not only the corpuscles of other species, but also those of healthy men. He further found that the hæmoglobin was destroyed and did not remain in solution as when destroyed by other agents. He also noticed that the globulicidal action was greatest in the case containing the least sodium chloride in solution in the serum. When this salt was increased, the globulicidal property was lessened and the patient recovered.

From the experiments detailed in this paper it will be seen that the corpuscles of an animal are not destroyed by every foreign serum. The serum of man and of the dog, two flesh-eating animals, is toxic and globulicidal to rabbits, while the serum of the cat had no effect upon the rabbit. The serum of man had no effect upon the dog.

In studying the subject of transfusion it was found by Panum and by Ponfick and others that sheep serum in large quantities is toxic to dogs.

Lamb's serum has been injected into human beings suffering from tuberculosis without any unpleasant result.

---

\* *Loc. cit.*

Rummo \* has studied the toxicity of different serums, but my observations seem to show that the toxicity is greater than stated by him. He found the toxicity increased enormously in acute infectious diseases.

In those cases where death occurred from the injection of either human or canine serum, I never found a chicken-fat clot in the heart. The ventricles were distended, the left with fluid blood, while the right often contained a soft, non-adherent, very dark clot, such as is formed just in the agonic period.

---

#### DISCUSSION.

Dr. HODGE. I have been greatly interested in Dr. Carter's paper, but, unfortunately for this discussion, have not worked in this department of physiology. I am glad to say, however, that we have a member present who has worked extensively in the related field of the germicidal properties of blood and serum, and Dr. Beyer has kindly consented to open the discussion.

Dr. H. G. Beyer, U. S. Navy, discussing Dr. Carter's paper on the globulicidal action of certain blood serums when injected into different animals, asked whether Dr. Carter had taken into close consideration the relative proportion of leucocytes to the red globules, as well as the absolute number present of each. For, inasmuch as any error creeping into the count of the red in case of an increase of the leucocytes would give rise to errors being multiplied by as many times as 1 cubic millimeter is contained in 6 liters of blood. Dr. Carter stated that while the leucocytes of the different classes changed in number and in their relations to themselves, their relative proportion to the red globules had not changed, and throughout his experiments remained the same. Dr. Beyer was satisfied.

Dr. Macallum objected to the term "globulicidal." It would appear that Dr. Carter's results might be very well explained as due partly to physical and partly to physiological processes. It is well-known that the isotonic coefficient of the red corpuscle of the animal is different from that of the red cell in another animal. When, therefore, the serum of one animal is injected into the blood of another the physical equilibrium is overthrown and red corpuscles disintegrate. This result, therefore, is a physical one. On the other hand, that serum of some animals when injected into those of another species, gives toxic effects seems to be definitely proved by the results of the experiments described by Dr. Carter. Dr. Macallum took exception to the view enunciated by Dr. Beyer, that observations tend to show that red cells originate partly from the white corpuscles. If the results of experiments of the last five years show anything at all, it is, that white cells never give origin to the red cells and, from the embryological point of view, the white cells never give origin to the red.

Dr. Beyer, continuing the discussion in answer to Prof. Macallum, stated that the literature within the period stated showed apparently, without doubt, that there are leucocytes that change into red corpuscles, namely, those that come from the bone marrow and a part of those coming from the spleen; those coming from the spleen are transformed into red partly within the spleen itself, partly after entering the blood current.

Dr. W. S. Carter said:

In reply to Dr. Beyer's question I would say that there was no alteration in the proportion of white and red blood corpuscles. With horse's serum in rabbits there was scarcely any alteration in the number of corpuscles of either kind, but there was a distinct change in the proportion of leucocytes. With dog's serum in rabbits there was scarcely any distinction of corpuscles, but when there was a distinction both kinds were affected so that there was change in the proportion of red and white

---

\* Trans. Tenth Internat. Med. Cong., Vol. II, p. 198.

corpuscles. In these there was a distinct alteration of the proportion of the different kinds of leucocytes. Human serum in rabbits caused rapid destruction of both kinds of corpuscles, there being no alteration in the proportion of white and red corpuscles. Here there was apparently an alteration in the proportion of leucocytes.

In reply to Dr. Macallum's remarks I would say that the term "globulicidal" seems a good term. It is used both by Daremberg and Buchner, and, as Buchner remarks, it is a property of the "half-living serum" and not a physical property. Certainly the corpuscles are greatly concerned in metabolism. There is a destruction of both red and white corpuscles, and under the microscope the changes of necrobiosis are seen in the white corpuscles when exposed to certain foreign serums. For these reasons it seems that "globulicidal" best describes the action of the serum.

---

## THE EFFECT OF LESIONS OF CERTAIN PARTS OF THE BRAIN UPON THE HEAT PROCESSES.

By EDWARD T. REICHERT, M. D.,

*Professor of Physiology, University Pennsylvania.*

In an article on thermogenic centers, read before the last meeting of the American Society of Physiologists and subsequently published in the University Medical Magazine for March, I briefly reviewed the experimental work thus far published which seemed to bear directly upon the nerve centers specifically concerned in the production of heat, and reported a new series of investigations, showing the location of the automatic thermogenic centers. The chief conclusions arrived at were (1) that the automatic thermogenic centers are located in the spinal cord; (2) that the cruciate and Sylvian centers in the cortex cerebri are thermo-inhibitory; (3) that the caudate nuclei and medulla oblongata contain thermo-accelerator centers; (4) that no specific heat centers probably exist in the optic thalami; (5) that specific thermotaxic centers, i. e., centers having a common control over heat production and heat dissipation, do not exist.

A number of points in connection with that study obviously needed further investigation, as, for instance, the conflicting statements of White as opposed to those of all other recent investigators relative to the physiology of the brain cortex in connection with the heat mechanism; the assertion of Ott that injury of the white matter immediately in front of the caudate nuclei is followed by a marked rise of temperature; the conflicting beliefs regarding the existence of heat centers in the optic thalami; the effects of injuries of the cerebral peduncles upon the heat processes; the effects of injuries of the pons upon the heat processes; the effect of pyretic and antipyretic drugs upon the heat functions after injuries of certain of above parts. These, together with other suggestions of seemingly minor importance, lead me to begin several series of investigations.

In the present inquiry two classes of experiments were performed; in one, complete transverse sections of certain parts at the base of the brain were made, and in the other the same parts were punctured. Sections were made with the idea of cutting off the influences of higher from lower parts and punctures were made for the purpose of definite localization of heat centers, or bands of heat films. I have not attempted localization by means of the injection of caustic solutions because such a method is generally far inferior to puncturing. Unfortunately, I have not been able to complete this work in time to report the results in full and in the present communication I can only offer the records of a series of sections.

In the study of the effects of lesions of the nerve centers upon the heat mechanism it is necessary to keep in view the fact that injury of almost any part of the cerebro-spinal axis may be followed by a more or less marked rise of temperature,

which may continue for hours, or even days, and which is particularly likely to occur, if the injury is complicated by much hæmorrhage, the pressure of a clot, shock, laceration of the tissues, etc. Besides this, a fertile source of error may exist in the marked and unaccountable fluctuations which occur under perfectly normal circumstances in the bodily temperature of rabbits, cats, guinea pigs, and dogs—the animals almost solely employed in this sort of investigation. The heat processes in dogs seem to be of greater stability than those in the other animals referred to, and on that account chiefly I have chosen them for this research. The mere fact that the heat mechanism may be materially influenced by injuries of any part of the nerve centers renders it evident that no portion of the brain or spinal cord should be concluded to be specifically concerned in the heat processes unless the phenomena produced by operations upon it are distinctly more marked than those which are observed when other but different parts are affected and unless the results are fairly constant and positive and the lesions properly localized.

In some of the experiments in the present series, observations were made only of the temperature; in others, records of temperature, circulation, respiration, and motor reflexes were obtained, while in others the method was calorimetrical. In all of the experiments strong healthy dogs were used. The technique of the operations was in all cases the same, unless specifically noted. The animals were anæsthetized with ether, chloroform, or a mixture of both; a small trephine opening was made in the side of the skull opposite to and on a level with the upper surface of the structures to be cut; the membranes were punctured; a slightly bent probe, 1 mm. thick and 2 mm. wide, was inserted horizontally and pushed across the brain until the skull on the opposite side was reached, and then with a downward sweeping movement all the cerebral mass below the probe was completely severed. A certain amount of hæmorrhage always occurred, but this was always very slight, and by properly inclining the head for a few minutes immediately after the operation drainage was facilitated and the pressure from a clot in a large measure prevented. Temperatures were seldom taken before the operation because the struggles of the animal, as well as the direct influences of the anæsthetic, so affect the heat processes that the record as a standard is more or less of a fictitious value. By means of sensitive thermometers, temperatures were obtained within three to five minutes after the section. With the exception of the calorimetrical experiments the thermometer was retained in the rectum throughout the entire periods of observation.

The experiments may be divided into six classes, distinguishable by the region of section (1) the frontal lobes just anterior to the caudate nuclei; (2) the corpora striata; (3) the optic thalami; (4) the crura cerebri; (5) the pons.

For many reasons it would have been desirable to have included a number of experiments upon the cortical heat centers of Eulenberg and Landois, and of Ott, especially so since White, in a recent communication (*Journal of Physiology*, XII, 1891, p. 233), gives results which lead him to reach conclusions in opposition to those of all other recent investigators upon these parts. White believes that lesions of the cruciate centers (Eulenberg and Landois) do not, or but slightly, alter rectal temperature. Regarding the Sylvian center (Ott), he concludes that its injury may cause irregular rises of temperature, which are quickly produced and last but for a short time; sometimes several rises and falls occur after one operation. He was induced to believe, considering the irregular variations and rapid character of the changes of temperature following these lesions, that certain parts are concerned in maintaining the balance between heat production and heat dissipation; in other words, of the nature of the hypothetical thermotaxic centers. White's results and conclusions do not, however, seem to be in entire accord. Thus, in his experiments on the cruciate region a rise of temperature occurred in every instance after the operation, varying from  $0.4^{\circ}$  to  $2.8^{\circ}$  F.; and in those on the Sylvian areas, in 18 out of 21 there was a rise—in 6 of less than  $1^{\circ}$ , in 3 between  $1^{\circ}$  and  $2^{\circ}$ , in 9 from  $2^{\circ}$  to less than  $3^{\circ}$ , and in 3 from  $3^{\circ}$  to  $4^{\circ}$ ; the average rise being  $1.62^{\circ}$  and the greatest  $3.6^{\circ}$ .

It seems, therefore, that White's results are rather in accord than conflicting with those of other investigations. There is, consequently, at the present time no sufficient evidence to weaken the belief that there are specific heat centers in the cruciate and Sylvian regions, and that both are thermo-inhibitory.

My experiments show that sections of the basal parts of the brain, even though the animals are thoroughly anæsthetized, generally severely affect the thermal, circulatory, respiratory, and motor reflex functions, and that, in a majority of instances, the shock to the respiratory centers is so great that the animals succumb within a few minutes to failure of the respiratory movements. If, however, artificial respiration is maintained the immediate effects of the shock pass off and, within a period varying from less than a minute to an hour or more (usually from five to ten minutes), automatic respiration is regained. The respiratory centers generally show for hours that their operations are disturbed, as is evident in irregularities in the depth and frequency of the respiratory movements, which frequently occur throughout the successive hours of observation. Indeed, it is not uncommon for spontaneous respiration to cease and after a time to be resumed, only again to cease and be resumed, and so on many times during the four or six hours after the section. As a rule, it seems that the nearer the sections are to the medulla oblongata the more profound and lasting the effects upon the respiratory centers. The circulation is always sooner or later materially affected. Sometimes the heart's action, immediately after the operation, is completely inhibited, the arrest usually lasting for but a few seconds, although in one experiment it was for thirty-seven seconds. I have never seen death result from permanent inhibition. That this inhibition is due to influences exerted through the inhibitory centers is evident in the fact that it was never present after section of the pneumogastric nerves. In some experiments these nerves were cut before the brain section was made, and in others during the existence of the inhibition. In the former, inhibition did not occur; and in the latter, it at once ceased.

In many of the experiments, sudden changes in the rapidity and force of the heart's beat occurred during the successive hours of observation, and without obvious cause. Sometimes within a second or two the heart's action would become enormously altered, thus in one case it fell from 264 to 192 beats per minute within a few seconds; shortly after this it suddenly increased from 153 to 240. The arterial pressure is variously affected, generally showing a tendency to slight increase during the early period of the experiment and to a decrease later. But there is a great lack of uniformity. Owing to the sensibility of the respiratory centers to the injury to the parts subjected to section, it was my practice, after anæsthetization, to insert a tracheal tube, and as soon as any sign of failure of respiratory movements occurred, to begin artificial respiration, maintaining this until spontaneous respiration returned with sufficient strength to carry on the function.

After these operations the dogs usually remained in a condition of stupor and seldom lived for more than six or eight hours, many of them succumbing in less time and some living from two to three days.

(1) LESIONS OF THE FRONTAL LOBES JUST ANTERIOR TO THE CAUDATE NUCLEI.

Ott states (*Therapeutic Gazette*, September 15, 1887), apparently from the results of a single experiment on a rabbit, that transverse section of the white matter 1 mm. anterior to the ends of the caudate nuclei is followed by a rapid rise of temperature, which lasts until the third day. This, he also states, is the most anterior part of the brain, which will give a marked rise of temperature when injured. On the other hand, the experiments of Aronsohn and Sachs (*Pflüger's Archiv f. Physiologie*, LVI, S. 237), and White (*Journal of Physiology*, XI, 1891, and XII, 1891), lead to the belief that injury of this portion of the brain is not followed by a rise of temperature.

In two experiments in which I made section just in front of the ends of the caudate nuclei, barely escaping them, the temperature fell in both. Records were made of temperature, pulse, arterial pressure, and respiration, which will be found in the following tables. In experiment 1 the section was less than 1 mm. from the nuclei, and in experiment 2 just 1 mm. in front of them. While both circulation and respiration were materially affected in both there is no apparent connection between the effects on them and the fall of temperature. If, however, the section involves even the tips of the nuclei the effects on temperature are very different, as are illustrated in experiments 3, 9, and 10, in which from 1 to 2 mm. were cut off, in every one of which a rise of temperature was recorded. The evidence, therefore, seems to point conclusively to the belief that the rise of temperature noted in Ott's experiment was due either to injury to the ends of the caudate nuclei or was an exceptional result.

## (2) LESIONS OF THE CORPORA STRIATA.

The experiments of Ott (*Journal Nervous Diseases*, April, 1884), Aronsohn and Sachs (*loc. cit.*), Girard (*Archiv. de Physiologie*, VIII, 1886, p. 281), Baginsky and Lehmann (*Virchow's Archiv*, CVI, 1886, S. 258), and White (*loc. cit.*) all indicate that lesions of the striated bodies are generally followed by a marked increase of bodily temperature, and some of the observations show that this increase is due to increased heat production consequently leading to the belief that these structures contain thermo-accelerator centers. The most extensive of the above investigations is by White embracing 23 experiments in his first paper and 4 in his second. In 3 of the 27 no rise occurred, and in 2 there was a fall; in the remaining 24 the temperature reached as high as from  $104^{\circ}$  to  $106.8^{\circ}$ ; in 7 it was  $106^{\circ}$ , or over.

In my own investigations section was made through these bodies in 12 experiments, in 6 of which calorimetrical methods were employed. In the first 6 the sections were made at the following levels from the anterior extremities of the caudate nuclei: Experiment 3, 2 mm.; experiment 4, 5 mm.; experiment 5, 6 mm.; experiment 6, 9 mm.; and in experiments 7 and 8, 12 mm. A rise of temperature occurred in every experiment, although the alterations were by no means uniform in general characters or in degree. The rises were, respectively,  $0.36^{\circ}$ ,  $0.98^{\circ}$ ,  $4.37^{\circ}$ ,  $3.4^{\circ}$ ,  $3.08^{\circ}$ , and  $2.2^{\circ}$ . Possibly in experiment 8 the rise might have been greater had not 3 grams of phenocoll hydrochlorate been intravenously injected, although this is not probable judging from the results of other experiments in which antipyretics were administered.

In experiment 3 the increase of temperature passed away within twenty-five minutes after the section, and was followed by a marked fall, which progressed until the end of three hours, showing a decrease of  $2^{\circ}$ . In experiments 4 and 6 there was a primary fall followed by a rise; in the former the rise was followed by a fall, and in the latter it continued to increase until death. In experiment 5 the rise set in at once and steadily continued until death, the temperature increasing within four hours from  $39.68^{\circ}$  to  $44.05^{\circ}$ . In experiment 7 there was a slight primary rise; then a slight decline, but not to the normal; then a marked rise followed by a fall. In experiment 8 the temperature rose steadily for one and three-quarter hours, and then slightly declined. What influence the injection of the phenocoll had is not positive, although as before stated, it is doubtful if it at all affected the results. The average rise of temperature in the 6 experiments was  $2.39^{\circ}$ , the minimum being  $0.36^{\circ}$ , and the maximum  $4.37^{\circ}$ . In the remaining 6 experiments the hourly records of bodily temperature are, of course, insufficient to show the maximum and minimum fluctuations, but in every case an increase was noted, varying from  $0.34^{\circ}$  to  $4.1^{\circ}$ . Doubtless, with but a single exception, the rise was materially greater. The calorimeter and methods employed were described by me in the *University Medical Magazine* for January, 1890.

The sections were at the following levels from the anterior margins of the caudate nuclei: Experiment 9, 1 mm.; experiment 10, 2 mm.; experiment 11, 6 mm.; experiment 12, 8 mm.; experiment 13, 10 mm.; and experiment 14, 14 mm.

A study of these results shows as important facts (1) that there is in the different experiments no general uniformity in the alterations in heat production, heat dissipation, and bodily temperature; (2) that both heat production and heat dissipation are more or less independently affected, although the alterations in the latter are largely dependent upon those in the former; (3) that in every experiment there occurred at some period an increase of bodily temperature; (4) that the rise of temperature was due to an increase of heat production.

In 4 experiments (Nos. 9, 11, 12, and 13) heat production was increased during the first hour after the section; heat dissipation was also increased in each, but, with a single exception, to a far less degree than heat production, thus indicating that the alterations in dissipation were of a compensatory nature. In 2 experiments (Nos. 10 and 14) both heat production and heat dissipation were diminished during this period, heat production being more affected than dissipation, this again indicating that the alterations in dissipation were dependent. During the subsequent hours the relations between the curves of production and dissipation were of an uncertain character and indicate that during this period the alterations in dissipation were in a measure independent of those in heat production.

In 2 experiments (Nos. 11 and 13) the maximum rise of temperature was noted at the end of the first hour, the increases being respectively  $0.82^{\circ}$  and  $1.88^{\circ}$ ; in 1 (No. 9) the highest temperature was noted at the end of the third hour, the increase amounting to  $0.54^{\circ}$ ; in 2 experiments (Nos. 10 and 14) the maximum was noted at the end of the fourth hour, the rises being  $0.48^{\circ}$  and  $2.19^{\circ}$ , respectively; and in experiment 12 the increase amounted to  $3.43^{\circ}$ , recorded at the end of the fifth hour, the average time of the occurrence of the maximum increase being two hours and fifty-three minutes after the section.

Therefore, in every one of 12 experiments in which the corpora striata were cut, the level of the section varying from 1 to 14 mm. from the anterior extremities of the caudate nuclei, an increase of temperature occurred, the minimum being  $0.36^{\circ}$  and the maximum  $4.37^{\circ}$ . In the first six of the series, in which temperature records were frequently taken, and in which these records are more valuable for showing the maximum effects, the average rise was  $2.39^{\circ}$ .

A careful comparison of the records of the different experiments leads to the belief that the temperature is most profoundly affected when the section was located from 6 to 12 mm. from the anterior extremities of the caudate nuclei.

### (3) LESIONS OF THE OPTIC THALAMI.

Both Ott (*loc. cit.*) and Baculo (La Riforma Medica, 1890, pp. 1568 and 1574) state that lesions of the optic thalami cause a rise of temperature, and believe that these ganglia contain heat centers. Ott's experiments were made by puncture or section, while those of Baculo were by the injection of bismarck brown and bichromate of potash, etc. White (*loc. cit.*), however, has obtained different results. In his first paper he reports 9 experiments made by puncture, in every one of which there occurred a rise of temperature; but in his second contribution, as a result of further and more cautious study, he reaches the conclusion that the thalami possess no power to cause an increase of temperature, and that when they have apparently done so, it has been owing to involvement of the corpus striatum.

My own experiments seem to be in accord with White's conclusions. In 2 experiments, in both of which the sections were in the posterior half of the thalami, the striate bodies not being injured, a slight but transient rise of temperature occurred, which was followed by a marked fall.

In experiment 15 the section was through the middle of the ganglia; the temperature rose only  $0.14^{\circ}$ , and then rapidly fell. In experiment 16 the temperature increased during the first eleven minutes  $0.1^{\circ}$  and then declined. In this experiment the section was 3 mm. from the posterior extremities of the thalami.

In one calorimetrical experiment, in which the section was 4 mm. from the posterior extremities of the ganglia, a decided fall of temperature, heat production, and heat dissipation was noted. Heat production was affected more than heat dissipation, so that the fall of temperature was doubtless due to a diminution of heat production.

The results of these three experiments are in striking contrast with those in which the striated bodies were cut.

#### (4) LESIONS OF THE CRURA CEREBRI.

There are extremely few experiments on record in which the temperature alterations were studied after section of the cerebral peduncles. Pflüger (*Pflüger's Archiv. f. Physiologie*, XII, 282, 333) states that after section of the crura behind the corpora quadrigemina, the temperature is sometimes increased and sometimes diminished. In one experiment by Wood (*Fever; A Study in Morbid and Normal Physiology*, Smithsonian Contributions to Knowledge, No. 357, 1880), partial section was followed by a rise. Fleishmann (*Wien. Med. Woch.* 1871, Nos. 6, 7, 8, 9,) found a diminution of 3° F. within a half hour. In 2 experiments by White (*loc. cit.*), a marked rise was noted in each, amounting to 3.4° and 2.2° F., respectively.

Of 20 experiments which I performed, in which special study was made of the temperature, the results of which will be found condensed in the following table, a rise was recorded in 16 and a fall in 4. The increase varied from 0.04° to 3.64°. In 12 it ranged from 0.04° to 84°, and in 4 from 1.2° to 3.64°. In 10 out of the 16 it was very transient. The region of section does not seem to exert any special influence; in experiments 18, 19, 20, and 25, the sections were close to the thalami, and the rises were 0.04°, 0.14°, 0.25°, and 2.94°, respectively; In experiments 24, 32, and 33, the sections were in the middle, and the rises amounted to 1.2°, 0.12°, and 0.4°, respectively; and in experiments 21, 22, 23, 26, 27, 28, 29, 30, 31, 34, 35, 36, and 37, the sections were all within 3 mm. of the pons, the rises being 0.84°, 0.12°, 0.08°, 0.65°, 0.54°, 0.55°, 1.3°, 0.07°, and 3.64°; in experiments 34, 35, 36, and 37, the temperature fell from the first.

Besides these, 28 experiments were performed by means of the calorimeter. In 5 (experiments 39, 40, 41, 42, and 44) the sections were within 4 mm. of the pons; in experiment 43 it was midway between the pons and optic thalami; and in experiments 45 and 46 it was close to the thalami. In 4 of the 8 a slight, transient rise of temperature occurred immediately after the section, which was followed in every instance by a profound fall. In the other 4 a fall set in immediately after the operation. A study of calorimetrical records renders it evident that the fall of temperature was due to diminished heat production.

#### (5) LESIONS OF THE PONS.

Tscheschichin (*Dw-Bois Reymond's Archiv. für Physiologie*, 1866, s.) in a single experiment records that division of the medulla oblongata from the pons was followed at once by a marked increase of bodily temperature. Bruck and Günter (*Pflüger's Archiv. f. Physiologie*, III, 1870, s. 578) in 23 experiments in which the pons was severed at its junction with the medulla, or in which it was punctured, state that in 11 an increase of temperature occurred, and in 12 a diminution. In 11 experiments by Ward (*loc. cit.*), in which partial or complete section was made, an increase occurred in 8 and a decrease in 3. In 2 of the former the rise amounted to 3.25° and 4.88°, respectively. Of 7 experiments (Nos. 47 to 53 inclusive) in which I made section at this point, in 6 the temperature was increased, and in 1 it was diminished. Two of the experiments were calorimetrical. In experiment 47 the animal lived for less than one hour, and the temperature fell steadily from the time of the section. In experiments 48, 49, 50, and 51, the rises were, respectively, 3.48°, 0.27°, 2.87°, and 4.34°, an average of 2.74°. In the two calorimetrical experiments

(Nos. 52 and 53) the maximum increases were  $0.61^{\circ}$  and  $0.76^{\circ}$ , although the figures doubtless do not represent the full degrees of actions. The results of the latter experiments show clearly that the elevation of temperature in this series, as in the others in which this change was noted, was due to an increase of heat production.

In conclusion, an analysis of the results of those experiments of the different series in which the temperature alterations were specially considered, gives the following data:

|                                                                                | Section anterior<br>to striated<br>bodies. | Section of stri-<br>ated bodies. | Section of optic<br>thal. | Section of crura<br>cerebri. | Section of<br>pons. |

By comparison and direct results, these figures clearly indicate that the striated bodies and pons are in some important way connected with the heat mechanism, either of the nature of nerve centers or nerve tracts; and, moreover, the fact that the increase of temperature is due to increased thermogenesis, and this to excitation and not loss of inhibition, leads inevitably to the belief that the formation is thermo-accelerator.

It is obvious that much work remains to be done before we are in a position to definitely state the meanings of the records of these important experiments, but the records, as far as they go, fully substantiate the claims made by me in a recent communication, to the effect of the locations and functions of specific heat centers.

## THE RELATION OF THE NERVOUS SYSTEM TO HEAT PRODUCTION.

By ISAAC OTT, M. D.

In the Journal of Nervous Diseases I have classified the centers concerned in heat regulation as thermotaxic, whether concerned with thermogenesis, thermolysis, or thermo-inhibition. In some experiments just made with atropine it was found to act upon the cerebral thermotaxic centers and not on the spinal. It occurred to me that perhaps the heat was nearly all generated in the tissues. To determine this, it would be necessary to remove so much of the nervous system as possible and then determine the amount of heat produced. Cats were selected for this purpose. They were put into the calorimeter for two hours, when they were removed, etherized, and portions of the spinal cord destroyed. The calorimeter employed was the one improved by me, and whose error is only 5.4 per cent. After the animal was under the ether an opening was made into the vertebral canal in the upper dorsal region and the cord destroyed downward by means of a stiff wire as far as the lumbar vertebrae, where a second opening was made in the vertebral canal and the remainder of the cord destroyed. Then the animal was immediately returned to the calorimeter and the heat production studied for four more hours. After this he was killed with chloroform. It was found that sections below the fifth dorsal were nearly always followed by recovery; if above, near the last cervical vertebra, there was often arrest of the heart, and death. It was found that after sections above the fifth dorsal that the heat produced fell to nearly 1 or 2 units, but afterwards rose to about one-third to one-half of the normal output (experiment 1). If, however, the section was just at

the fifth dorsal, then nearly always the heat production remained but little below the normal amount (experiment 2). In one case (experiment 3) it exceeded the normal amount. Eleven experiments were made and they confirmed the preceding statements. The inquiry now arises, how are they to be explained? It is known if you divide the spinal cord between the fifth and sixth dorsal nerves, that is, where the splanchnic fibres divide from the cord, then the blood vessels of the skin and of the abdomen dilate and the blood-pressure falls greatly. If the section is made above the level of the second dorsal nerve, then in addition to the above vaso-motor paralysis there is a dilation of the vessels of the face and head which still further reduces the arterial tension. The cardiac accelerator nerves also leave the spinal cord by the second and third dorsal nerves and possibly to some extent by the fourth and fifth. While the vaso-constrictor centers of the body are in the dorsal cord, the vaso-dilators centers are spread throughout the cord.

When I destroy the cord below the fifth dorsal vertebra, I cut off vaso-constrictors, the splanchnics, and also annihilate the vaso-dilators, mainly going to the muscles below this point. This section causes a loss of muscular tonus and a great fall of arterial tension. If I destroy the cord about the first or second dorsal, then all the vaso-constrictors are destroyed and nearly all the vaso-dilators. The animals who died seemed to be shocked, probably by the reflex cardiac inhibition and partly by the great vaso-motor paralysis. In cats I made some blood-pressure experiments, and found that the above-mentioned sections and destructions of the cord greatly reduced the blood-pressure. Now, it seems to me, that the spinal thermogenic centers play but a small part in the heat production of these experiments. In an animal, after death, I made a transverse section of the whole body at the fifth dorsal vertebra, and the weight of the body anterior to this section was 3 pounds, while the body weight posterior to the division was a little over 5 pounds. In this case there could be no spinal thermogenic centers connected with the posterior part of the body, hence we can only have their effect upon the anterior part of the body—that is, the 3 pounds or three-eighths—while the five-eighths have only the tissue heat without any nervous action. Now, if we assume for the sake of argument that the heat produced after a section at the fifth dorsal is greatly due to spinal centers, then we must assume that the normal three-eighths of the body can produce as much heat as the normal eight-eighths of the body with an intact nervous system. This, to my view, is an absurdity. It seems to me much more rational to assume that the heat is nearly all produced in the tissues of the body and that the spinal thermogenic centers are of small value. That after the animal is greatly shocked by the section above the fifth dorsal it is easily understood that thermogenesis is greatly arrested. Admitting these facts, it is readily seen that the heat is mainly produced in the tissues and that the whole nervous system concerned in heat regulation is thermotaxic. If the temperature falls below  $98.4^{\circ}$  F., then impulses are sent by the cerebral centers to the spinal centers and more heat is generated. If the temperature is above  $98.4^{\circ}$  F., then the thermo-inhibitory centers of the cortex act or the tuber cinereum may be stirred up, and thermolysis be increased by augmenting the rate of respiration.

Dr. B. Baculo, of Naples, holds that the thermo-inhibitory centers act directly upon the basal thermogenic centers. While I have published experiments supporting this view, I think there is little doubt but that they also act directly upon the spinal thermogenic centers.

Dr. E. T. Reichert believes the spinal thermogenic centers to be of a high value, and played upon by cerebral centers, like the heart is played upon by the cerebral nerves. But these experiments show that the cerebral centers are of high value and the spinal thermogenic, *per se*, are of little value.

Dr. Baculo, of Naples, noted an increase of temperature after the injection of an irritant into the corpora quadrigemina. Baculo believes these bodies contain thermogenic centers like the tuber cinereum of the midbrain. The experiments in this

paper show that the arterial tension can be greatly lowered and heat production not be affected. In a previous paper I explained this rise of temperature after injury of the corpora quadrigemina as due to lessened tension and changed rate of respiration, but these spinal experiments have changed my mind. What the correct explanation is of this rise after an injury to the corpora quadrigemina remains to be worked out. That the tuber cinereum contains thermogenic centers is shown by the experiment where, with a fine dental drill, I punctured the tuber through the mouth, and obtained a temperature of  $109^{\circ}$  F. It should be remembered that what I have described as the thalamic heat center and the heat center about Schiff's expiration crying center, as well as the thermo-polypnœic center are all seated in the tuber cinereum. One of the most certain signs that you have punctured the tuber is the accelerated respiration, accompanied with a considerable and rapid rise of temperature. In puncturing through the mouth the fibre theory of some writers is demolished, as you injure no fibres in this operation.

That transverse sections in front of the caudate nucleus, or of the caudate nucleus itself, producing a rise of temperature and increased heat production, will show the presence of heat centers is conceded; but posterior to the corpus striatum no transverse section, even if accompanied with rise of temperature and increased heat production, will localize any heat center in the pons or medulla, as you have removed part of the heat-regulating apparatus anterior to the section, and very naturally the temperature rises and heat production is increased. It is only by well-localized punctures into gray matter, producing considerable rise of temperature and augmentation of heat production, that you can infer the presence of a thermogenic center at the base of the brain. That injury of the crura will cause a rise of temperature is true, but here you may, by puncture, injure both thermo-inhibitory and thermogenic fibers, so that no localization of a thermogenic center can be inferred.

It seems to me that in the cortex the cruciate center of Eulenberg and Landois, and the Sylvian, are thermo-inhibitory; that the basal thermogenic centers are located (1) in the caudate nucleus; (2) in the gray matter beneath and in front of the corpus striatum; (3) in the tuber cinereum, and that these centers act upon the tissues through spinal centers when the metabolism needs to be accelerated or retarded in activity, to develop the amount of heat necessary to keep the temperature at  $98.4^{\circ}$  F., and this is an act of thermotaxis. Therefore I believe the function of all these centers, thermogenic and thermolytic, to be heat regulating or thermotaxic.

## EXPERIMENT I.

[Cat; weight, 3.34 pounds; section of cord at seventh cervical and destruction below this point.]

|                                    | H. P. | H. D. | R. T.              |                 |

DISCUSSION.

Dr. Beyer said that there was no room for further doubt of the existence of specific heat-producing, heat-dissipating, and heat-regulating centers in the brain as well as in the spinal cord. In the case of the heart and its accelerating and inhibitory centers in the medulla, we have quite an analogous condition only, that work is produced by these cardiac centers which are definitely located, and in the case of the heat centers heat is produced under normal condition, which is only another form of the same energy. In one case we obtain work by the peculiarity of the connection of these centers with peripheral organs; in the other case we attain heat for similar reasons.

Dr. Macallum observed that in experiments on the central nervous system much more happens than what appears on the surface, as is shown by the condition called "shock." This complicates the results obtained, although the experiments of Ott, Reichert, and others show distinctly that there are "centers" whose function is that of controlling the production and dissipation of heat. All who have studied the history of our knowledge of the vaso-motor centers will remember the discussions on the question of the existence of subsidiary vaso-motor centers in the cord, and even along the blood vessels. Many of the results which have been obtained in those experiments have been due to "shock." If we bear in mind, then, that a similar condition occurring after experiments on the central nervous system should manifest itself by some results which possibly have been attributed to influencing the central heat "centers" one may, for all this, well believe in the existence of such centers, although we may further allow that their delimitation and localization have not been exactly determined.

## HOW DOES ATROPINE ELEVATE THE TEMPERATURE OF THE BODY?

By ISAAC OTT, M. D.

If atropine is given to an animal it will cause a rise of temperature varying from  $1.5^{\circ}$  to  $6.8^{\circ}$  F., provided the temperature of the ambient air is elevated. If, during the elevation of temperature, the sciatic is electrically irritated, a greater rise ensues. This rise after sciatic irritation is not sudden as normally takes place, but rises gradually and continues after the irritation for two hours, after which it gradually falls. It was found that while the temperature was rising the arterial tension was falling. When it was determined by the calorimeter, it was found that the increase of temperature was accompanied by an increased production and augmented dissipation of heat. I have heretofore, on account of the spinal stimulant action of atropine, inferred that the elevation of the temperature was due to spinal stimulation. To experimentally determine the seat of action I have used cats which are well suited to show the elevation of temperature. Thirteen experiments were performed. When the cord was cut at the atlas and atropine injected per jugular there was no rise of temperature. Several repeated experiments demonstrated that the rise was not spinal.

The next experiment was made after a transverse section, just in front of the medulla oblongata, the carotids being previously ligated; then a rise of temperature ensued, after the use of atropine, of about  $1^{\circ}$ . But normally a rise of temperature ensues after section in front of the medulla, because the great regulating centers of the brain have been cut off. How are we now to differentiate between the normal rise and that rise after the drug? After the atropine the rise is only  $1^{\circ}$ , but when the animal's nervous system is intact the rise is often  $6.8^{\circ}$  F. I have also made some sections in front of the pons varolii and given atropine. Here we also have a rise of temperature without atropine. With the atropine the highest rise was  $2.2^{\circ}$  F., after section in front of the pons, which is not more than would be expected normally. After careful consideration of the results, it seems to me difficult to speak accurately as to the cerebral center affected. The slight rise of temperature after puncture of the medulla or pons varolii in the rabbit have not led me to believe in the existence of thermogenic centers in these bodies. Until we have definitely determined the existence of heat centers in these organs it seems to me useless to assume that atropine acts upon them. Although not directly connected with this subject, yet I hope it will not be amiss to speak of the value of atropine in shock, as in the preceding paper I have demonstrated that during the first hour of shock heat production is nearly zero, and as atropine is an augmentor of heat production we have an additional proof of what is practically known, that atropine is of great value in shock. Cocaine is also an accelerator of heat production and would without doubt be of great utility.

## EXPERIMENT I.

[Cat; tracheotomy; spinal cord cut just below atlas.]

## NOUVELLES RECHERCHES SUR LES CENTRES THERMIQUES AU SUJET DE LA THERMOGÉNÉSIE THERMODYNAMIQUE.

Par le Dr. B. BACULO.

*Institut de Pathologie Générale de l'Université Royale de Naples.*

## GÉNÉRALITÉ SUR LA THERMOGÉNÉSIE.

Les manifestations thermiques sont liées aux phénomènes bio-chimiques qui se produisent dans la texture intime des tissus. L'influence dynamogène du système nerveux, qui est le premier facteur dans le mécanisme de la régulation de la chaleur, est souveraine sur ces phénomènes.

La température des organismes s'élève sans cesse selon le progrès des pécilothèrmes aux oméothermes; dans ces derniers il y a la régulation de la chaleur. Cette fonction n'apparaît dans les organismes animaux si le système nerveux n'a pas atteint une perfection, soit dans l'aggrégation des éléments istogénétiques, soit dans sa structure intime.

Tout cela est bien clair en considérant le développement du système nerveux dans les pécilothèrmes, et même dans les oméothermes, en regard du progressif perfectionnement que ce système acquiert dans la période de développement des mêmes, car pendant que se développent les pouvoirs qui causent la thermogénésie animale se perfectionne la thermo-régulation, et la température des animaux adultes s'égale au degré qui appartient à la classe et à l'ordre.

La régulation thermique est donc liée au développement et au perfectionnement du système nerveux.

Mais cette fonction le système nerveux l'explique en *toto*, ou par centres et par voies nerveuses spéciales, ou mieux par des mécanismes spéciaux?

Existe-t-il une régulation thermique indépendante du système vaso-moteur?

## EXISTE-T-IL DES CENTRES THERMIQUES?

Voilà les questions que je me suis proposé de résoudre après des recherches expérimentales.

Sur la première. Dans les névroses de l'isthme en bas l'existence de centres thermiques est beaucoup douteuse, car j'opine que les phénomènes d'élévation ou d'abaissement de la température jusqu'à présent remarqués sont liés à des désordres vaso-moteurs.

L'existence au rebours des mêmes centres dans les névroses de l'isthme en haut est un fait positif, assuré par des recherches expérimentales.

## TECHNIQUE EXPÉRIMENTALE.

J'ai cherché à conduire mes recherches sur ce sujet dans les conditions les plus physiologiques que possible de l'animal: en localisant exactement la lésion par une technique spéciale; \* en marquant de courbes thermiques après une longue période d'observations; et en usant des propres appareils thermo-électriques, dont l'un a été construit à dessein.

Vraiment je n'ai pas usé dans la technique expérimentale la trépanation et la chloroformisation en choisissant des lapins très jeunes, et en ayant auparavant bien étudié le rapport topographique entre les ganglions à la base du cerveau et la surface externe de la tête, j'ai pu léser les mêmes ganglions par diverses manières, dont la plus simple est avec une subtile aiguille de Pravaz, colorée à la pointe avec une solution de méthyl violet très saturée et séchée rapidement. Lorsqu'elle parcourt son trajet à travers les tissus, cette aiguille ainsi apprêtée les colore, et à l'autopsie de l'animal on peut ainsi voir le point d'arrêt de l'aiguille, et son trajet.

\* Voyez: Nota preventiva "Centri Termici," Luglio, 1890. Tip. Salvati o seguente edizione della Riforma Medica, e l'altra pubblicazione col titolo "Se esistano Centri Termici e se esiste una regolazione termica indipendente dai vasomotori."

C'est ainsi que j'ai cru avoir bien localisé la lésion en la limitant à des points déterminés, sans causer de graves lésions collatérales, et en suivant, selon mon avis, la méthode la plus propre pour expérimenter dans les conditions de l'animal les plus physiologiques que possible.

Pour les mesures thermo-électriques j'ai usé les aiguilles d'Arsonwall et construit en outre un galvanomètre spécial, qui par le courant thermo-électrique qui se développe d'une de ses aiguilles mise en un médium à 38°, donnait un arc impulsif de 20°.

#### COROLLAIRES EXPÉRIMENTAUX.

Les résultats expérimentaux que j'ai obtenus sont: (1) En lésant le thalamo optique, on observe une élévation thermique générale avec prépondérance à la moitié correspondant à la lésion et à l'artum supérieur. (2) En lésant le tuberculum quadrigeminum antérieur, on observe une élévation thermique générale avec prépondérance à la moitié correspondant à la lésion et dans l'artum inférieur. (3) L'injection dans les ventricules latérales cause un abaissement de la température. (4) J'ai produit des lésions corticales, soit après piqure (toujours à l'obscur), soit en faisant une fenêtre au crâne et en injectant dans les lacunes ipoméningées de l'eau distillée colorée avec le méthyl violet, pour connaître l'extension de l'irritation corticale.

Les courbes thermiques sont signées par les appareils thermo-électriques, et ont démontré constamment un abaissement de la température qui dure pendant plusieurs jours.

#### CENTRES THERMO-INHIBITOIRES CORTICAUX ET CENTRES THERMOGÈNES BASILAIRES.

Les centres thermiques sont donc distingués en thermo-inhibitoires, qui sont les corticaux, et dans le lapin se trouvent dans le lobe fronto-parietal; et en thermomoteurs ou dynamo-thermiques ou encore thermogènes, et se trouvent dans les ganglions basilaires.

Je ne peux entrer dans l'étude critique des centres thermiques, et par suite, malgré mon désir, je ne peux énoncer les autres faits qui rendent positif leur existence.

Je suis convaincu que le secret pour déceler les fonctions du cerveau (du grand coordinateur de tous les centres réflex ordonnés) consiste à expérimenter dans les conditions les plus physiologiques que possible.

#### OÙ EXISTE LE MÉCANISME RÉGULATEUR DE LA CHALEUR?

La mécanique régulateur dans la production de la chaleur ne réside pas dans la moëlle épinière. Ici existent vraiment dans les colonnes latérales les fibres thermiques qui partent des centres thermiques encéphaliques, pendant que la fonction thermo-inhibitoire appartient sans doute à l'écorce cérébrale, qui a de même la fonction d'inhibition des autres mécanismes réfléchis et ordonnés.

#### RÔLE DES VASO-MOTEURS DANS LA RÉGULATION DE LA CHALEUR.

Pour répondre à l'autre question: "Existe-t-il une régulation thermique indépendante du système vaso-moteur?" il faudrait l'éprouver expérimentalement: (1) Quelle importance a le système vaso-moteur dans la thermogénésie et dans la régulation thermique? (2) Si l'activité des centres thermiques agit directement ou par les centres vaso-moteurs?

Pour résoudre la première question, j'ai fait plusieurs recherches, qui m'ont donné les résultats suivants: (a) L'élévation thermique qui suit la neuro-parésis ou la nevro-paralisis vaso-motrice ne surpasse nullement la température moyenne du sang. (b) En excitant, ou en coupant le filet cervical du sympathique, dans le lapin, après avoir lié l'artère carotide, on n'observe pas de faits d'ipothermie, ou d'iperthermie locale. (c) Nulle quote-part d'élévation thermique n'est causée par la coupe du sympathique qui ne soit en rapport direct: avec une plus active circulation, avec le

degré de la chaleur accumulée dans le sang, et avec la différence de la température entre le sang même et le corps ambiant externe. (d) Les phénomènes de neuro-paralysie vasculaire ne modifient pas la courbe des variations ascensionnelles ou de descente de la température locale (oreille du lapin) qui suit, au contraire, l'allure thermique générale causée par l'offense des centres thermiques encéphaliques.

#### LES VASO-MOTEURS SONT LES DISTRIBUTEURS HYDRAULIQUES DE LA CHALEUR.

Le système vaso-moteur règle donc la distribution de la chaleur dans l'organisme, puisqu'il règle l'activité du cœur et le ton des vaisseaux. \*

Aussitôt qu'il règle l'hydraulique de l'organisme, il règle pareillement la dispersion de la chaleur.

#### RÈGLE EN MÊME TEMPS LA DISPERSION DE LA CHALEUR.

J'appelle cette régulation du nom de périphérique pour bien la distinguer de l'autre régulation que je nomme centrale. La première est sous le gouvernement direct du système nerveux de la vie végétative, tandis que l'autre est sous le gouvernement du système nerveux de la vie animale.

Le système vaso-moteur est néanmoins un facteur principal de la nutrition des centres thermiques, car il règle la circulation du plasma nutritif dans ces centres en réglant le ton des vaisseaux.

#### ACTIVITÉ DIRECTE DES CENTRES THERMIQUES.

J'ouvre la deuxième question: Les centres thermiques mettent-ils en exécution leur activité directement ou par les centres vaso-moteurs? J'ai fait pareillement des recherches expérimentales pour résoudre cette question.

Pour ôter tout doute, il fallait séparer l'élément vaisseau de l'élément nerf (je demande pardon de cette manière de m'exprimer) pour démontrer l'activité directe des centres thermiques.

#### EXPÉRIENCES.

J'ai pratiqué mes expériences de la manière suivante: Après avoir noté la température du lapin avec les appareils thermo-électriques, je le lie dans la douche de Schwann et bientôt l'animal entre dans un calme parfait; je note encore la température dans les mêmes points qu'auparavant; de suite je prépare la carotide et je note de nouveau la température de l'animal; je lie ensuite le thalamo optique par la méthode que j'ai exposée dans les précédentes publications, et j'observe, pendant un certain temps, la courbe de la température de l'animal dans les divers points notés précédemment, et après qu'elle s'est élevée, je lie l'artère préparée et j'observe ensuite l'allure des courbes thermiques dans les mêmes points qui ont été établis dès le commencement de la recherche.

Les planches I, II, III appartiennent à d'autres expériences que je n'ai pas publiées dans les précédents écrits, et tendent à rendre plus évidentes les inductions que j'ai faites sur cette deuxième question.

#### *Expérience C, (Série V.)*

Lapin rougeâtre, du poids de 11 grammes. Je fais la piqure du thalamo optique avec une aiguille de Pravaz teinte jusqu'à moitié de sa longueur avec une solution alcoolique très saturée de méthyl violet. L'aiguille est enfoncée de 3 mm. de la suture interpariétale, et à 2 mm. de la branche gauche de la suture lambdoïde, en enfonçant l'aiguille de 2.05 cm. environ, jusqu'à faire paraître des petites secousses convulsives. Je laisse l'aiguille ainsi pendant 5 minutes seulement, en donnant à la pointe des petits mouvements latéraux.

\*L'existence des ganglions idio-vasculaires d'Huizinga est bien connue. Les recherches de Ludwig et Mosso sur les vaisseaux des chiens récemment extirpés et parcourus d'un courant de sang; la restriction du calibre des artères jusqu'à l'occlusion complète de la lumière après des stimulus directs (Ludwig); la poursuite de la pulsation des veines dans la membrane volitante des chauve-souris après la recision de tous les nerfs (Luchsinger); tous ces faits affirment l'innervation locale des vaisseaux par ces ganglions idio-vasculaires.

Arrêté les premières secousses, qui durent environ 6 minutes; aucune autre ne paraissait pendant toute l'observation, et pareillement nulle vascularisation ne paraîtra dans les deux pavillons des oreilles du lapin. L'observation sur ce sujet dura 8 jours, après lesquels il fut tué en lui ôtant le sang. Voir la planche I pour l'allure de la courbe thermique et pour les autres remarques de la recherche.

*Autopsie.*—Lésion du thalamo optique gauche jusqu'au  $\frac{1}{3}$  de son épaisseur. Dans les autres organes on n'observe rien d'anormal.

*Résultat expérimental.*—La courbe thermique nous montre qu'après avoir lié la carotide gauche et pendant les jours successifs la température de la moitié gauche (côté correspondant à la lésion du thalamo) est restée en général plus élevée du côté droit, quoiqu'elle ait suivi la courbe thermique, ou l'allure propre aux lésions du thalamo optique.

Dans l'expérience suivante l'animal a été en observation pendant 34 jours, et la carotide a été liée 7 jours après la lésion du thalamo optique.

#### *Expérience L, (Série V.)*

Lapin gris du poids de 1,150 grammes. Je fais la piqûre du thalamo gauche comme il a été décrit ci-dessus.

Le lapin n'est pas pris de secousses convulsives, mais seulement d'hyperesthésie dans l'artum inférieur gauche, parce que l'animal crie avec force lorsque j'enfonce l'aiguille.

La perte de poids de l'animal est remarquable.\* Pour la courbe thermique et pour les autres remarques de l'expérience voir planche II. Le lapin fut tué, en lui ôtant le sang.

*Autopsie.*—Lésion très évidente du thalamo optique où la course de l'aiguille était tracée au milieu des tissus de la peau en bas. Dans les autres organes nul fait anormal n'est observé.†

La persistance de la coloration du méthyl violet après un temps aussi long est due à la technique expérimentale que j'ai suivie.

Le résultat de l'expérience confirme tout ce que j'ai observé dans l'autre recherche susdite.

L'expérience suivante n'a pas été suivie de l'autopsie car le lapin vit encore.‡

#### *Expérience M, (Série V.)*

Lapin noir du poids de 1,700 grammes. Je fais la piqûre du thalamo optique gauche comme il a été décrit ci-dessus. Après la piqûre, un mouvement de manège à droite est évident, lequel persiste pendant 11 jours et peu à peu diminue d'intensité, et le vingtième jour le lapin est en état de calme parfait, mais si on effarouche l'animal en le mettant en fuite, le mouvement de manège se reproduit de nouveau.

Nous rencontrons dans cette recherche un seul fait nouveau: c'est le mouvement de manège. Mais ce symptôme est dû à la lésion des fibres du pédoncule par la poussée de l'aiguille dans sa course.

En examinant la courbe thermique, planche III, on voit qu'à gauche, où a été liée la carotide, la température s'est élevée jusqu'à 12° au-dessus de l'état normal, et a suivi les modalités des courbes thermiques dans les lésions du thalamo optique.

#### RÉGULATION DES OBJECTIONS PAR DES AUTRES RECHERCHES EXPÉRIMENTALES.

Dans ces recherches je crois presque du tout éliminée l'activité vasculaire, puisqu'en ayant essayé ce sujet avec des autres expériences de preuve pour répondre à des objections scientifiques ou expérimentales, qui peuvent être mises en évidence en regard j'ai observé: (a) Que les effets de la blessure au col pour lier la carotide

\* J'ai remarqué ce fait même dans les autres expériences déjà publiées. Voir page 47 de la Monographie "Centri termici e Centri vaso-motori in ordine alla termodinamica regolarizzatrice in condizioni normali e patologiche. Napoli: Tip. Salvati. Marzo, 1871.

† Dans cette expérience, comme dans les autres déjà publiées, j'ai remarqué seulement tout ce qui touchait à la région encéphalique parce que je n'ai rencontré aucune lésion dans les autres organes. Pour cette raison les autopsies sont complètes.

‡ Le défaut d'autopsie ne diminue pas l'importance de cette recherche, parce qu'en suivant la technique expérimentale ci-dessus décrite, dans de longues séries de recherches, j'ai pu acquérir une sûreté technique dans les lésions des ganglions à la base du cerveau. Comme j'ai pu le démontrer à une commission de cette faculté de médecine, composée des professeurs de Martini, Antonelli, Armanni, qui furent présents à une des expériences dans laquelle l'autopsie du lapin fut pratiquée par le Prof. Armanni, et où la lésion du thalamo optique que j'avais produite en leur présence fut rencontrée parfaite.

N.B.—A. Ad ore 1.35 s' allaccia la carotida sinistra. B. Da questa misura in più furon sospese quelle della metà destra, osservandosi solo le sinistre per ragioni facili ad intendere.

D. .... Metà destra.

n'altèrent pas les résultats expérimentaux de la recherche parceque la ligature de la carotide a été pratiquée immédiatement après la piqure du thalamo optique, en certaines expériences, autrefois après plusieurs jours, et les résultats de la recherche (en regard des courbes thermiques) sont restés identiques. (b) En ayant lié la carotide et la sous-clavière, et en ayant ensuite coupé encore le filet cervical du sympathique dans le lapin. Je n'ai pas observé d'élévation thermique dans l'oreille du lapin. Ces expériences vont même à l'encontre de l'objection: que les anastomosis terminales des artères puissent réintégrer la circulation dans le champ des occlusions des artères, et même la température. Les faits expérimentaux démontrent sans doute le contraire de l'objection susdite, parceque la température dans le champ d'occlusion de la carotide est plus élevée que dans le côté, où la circulation est normale. Cette élévation même est évidente; soit après l'occlusion de l'artère, soit dans le parcours de plusieurs jours successifs (trente et plus encore). (c) Est-il même éliminé? Sans doute que l'anémie du centre lésé, en opérant comme une excitation, eût pu causer l'iperthermie parcequ'une ample vascularisation est établie pour le cercle artériel de Willis, et les phénomènes d'iperthermie sont continués pour plusieurs jours, après l'occlusion de la carotide. (d) Est-il éliminé encore? Sans doute que l'élévation de la température, après l'occlusion de la carotide, est causée par l'anémie des tissus (pour la ligature des grosses tiges artérielles) dans le côté de la tête répondant à la lésion, parceque, quoiqu'il soit bien connu que dans les parties de l'organisme où la circulation du sang est supprimée, la température s'abaisse rapidement, les expériences que j'ai faites ont démontré assurément un abaissement de la température dans les côtés où était close la circulation des grosses artères (carotide, etc.).

Voici les remarques expérimentales:

*Expérience R, (Série V.)*

Je note la température des oreilles et des deux côtés de la tête d'un lapin. Je clos ensuite la carotide gauche, et je note pour trois jours l'allure de la courbe thermique des mêmes places.

La température (voir planche IV) reste toujours plus basse qu'avant l'occlusion de l'artère.

*Expérience S, Série V.*

En un lapin je note la température de l'artum postérieur gauche, et ensuite je clos la crurale.

La température s'abaisse, comme il est remarqué dans la planche IV, où on voit l'allure des courbes thermiques des deux recherches susdites, qui démontrent précisément la faiblesse du doute sus-énoncé: Que l'élévation thermique qui suit aux lésions des centres thermiques ne puisse pas se rapporter à la fièvre de réaction du traumatisme cérébral, parceque le trauma avec la méthode que j'ai suivie est ramené aux limites les moindres que possibles.

C'est une piqure avec une mince aiguille de Pravaz, parce que j'ai banni de la technique la trépanation, la chloroformisation, etc. A la fin on ne peut pas mettre au nombre des fièvres de réaction les élévations thermiques remarquées au-delà de 30 jours.

Ces élévations thermiques sont plus remarquables parce que l'aiguille est enfoncée dans le tissu cellulaire sous-cutané, qu'à une température moins élevée que les autres tissus.

ENCORE SUR L'ACTIVITÉ DIRECTE DES CENTRES THERMIQUES.

L'activité dynamogène directe des centres thermiques est manifestée aussi par un autre fait:

Souvent il arrive dans les observations thermo-électriques que le galvanomètre ne marque pas le même arc, quoique avec la même vitesse on enfonce l'aiguille dans les tissus, on l'approfondisse pour la même longueur et on l'enfonce encore dans la même fenêtre cutanée pour observer la température de la même place.

Ce fait est-il causé par les oscillations de l'activité dynamogène directe des centres thermiques ou par les actions vasculaires?

Pour résoudre ce doute j'ai expérimenté ainsi: J'ai enfoncé l'aiguille thermo-électrique, trempée dans la paraffine et gardée à une température constante avec l'étuve de Meyer, et j'ai toujours noté un arc galvanométrique constant.

Bien, pourquoi dans les observations de la température de l'animal dans les conditions susdites, avons-nous des arcs galvanométriques qui varient de l'un à l'autre moment?

Voici les recherches que j'ai faites: Ayant, sur le thorax d'un lapin, appliqué le cardiographe, je recueillis sur un cylindre mu par le régulateur de Foucault le cardiogramme (le cylindre achevait un tour pendant 3 minutes).

Sur le cardiogramme je remarquai que l'intervalle entre les deux ordonnées systoliques était en moyenne presque 3 mm.

C'est pour ça qu'ensuite je disposai le signal électrique de Depretz en le réglant avec un métronome de telle manière qu'il traçât sur le même cylindre une courbe (parallèle au cardiogramme) avec une série d'interruptions qui se suivaient à 3 mm. d'intervalle, c'est-à-dire la distance qui était entre les deux ordonnées systoliques du cardiogramme.

Ayant ainsi disposé les choses, j'enfonçai sous la peau l'aiguille thermo-électrique dans le même moment complétant le circuit électrique entre le métronome et le signal électrique.

Il est bien évident qu'ainsi les interruptions du signal électrique étaient marquées sur le cylindre, que de systoles du cœur du lapin, toutes les fois que l'activité cardiaque ne variait pas pendant l'expérience.

Bientôt je pus remarquer que le cardiogramme, en plusieurs rencontres, coïncidait (pour la série des ordonnées systoliques) avec les interruptions du signal électrique, et en de tels rencontres l'aiguille thermo-électrique notait de très rapides oscillations de la température, rendues très évidentes par des arcs galvanométriques très variables sur le champ.

Quoique dans cette expérience les activités vaso-motrices ne soient pas tout à fait éliminées, néanmoins en la comparant avec les autres énoncées ci-devant, je crois qu'on peut en inférer que de telles variations si sensibles de l'aiguille thermo-électrique sont causées par l'activité dynamogène directe des centres thermogènes basilaires.

La très sensible variabilité des températures locales est un fait que j'ai remarqué autrefois.

La variabilité des arcs galvanométriques est évidente en passant de l'une à l'autre observation thermo-électrique, quoiqu'elles fussent environnées de toutes les finesses qui sont ordonnées par l'électro-technique.

Cette variabilité varie en certaines limites, qui suivent en général la courbe thermique ascensionnelle ou de descente que l'animal montre pendant l'expérience.

Par les expériences susdites et par les autres que j'ai publiées auparavant, je crois avoir des bases solides et je suis à la fois autorisé à confirmer tout ce que j'ai publié dans les années précédentes sur la fonction thermique spéciale des centres nerveux.

#### COROLLAIRES SUR LA RÉGULATION DE LA CHALEUR.

Ayant démontré l'inhibition thermique corticale sur les centres basilaires, de même que le manteau cortical a l'inhibition sur tous les centres automatiques et ordonnés, qui sont au-dessous dans la névraxe, il est bien claire: (1) Que la régulation de la chaleur est due à l'équilibre entre des forces opposées qui s'expliquent entre les centres thermo-basilaires (thermogènes) et les centres cortico-inhibitoires-thermiques. (2) Que selon la prépondérance de l'activité fonctionnelle des premiers sur les autres il y a hyperthermie ou hypothermie. (3) Que la somme des tensions dynamiques, thermiques et partielles, causées par l'excitation de chacun des centres thermiques, doit être égale à la tension de tous les centres à fonction homologue.

Voici l'effet utile qui résulte de l'énergie de tels centres, symbolisé avec la formule:

$$CT_a + CT_b + CT_c = CT (a + b + c),$$

ou CT est le symbole d'un centre thermique, et *a*, *b*, *c* sont les symboles de chacun des centres susdits (corps striatum, thalame, etc.).

Voici la régulation que je nomme centrale, dans le domaine du système nerveux de la vie animale.

#### MÉCANISME DE LA RÉGULATION DE LA CHALEUR.

Physiologiquement la fonction régulatrice de la chaleur est une, mais pour en entendre la mécanique j'ai divisé les deux principaux mécanismes (qui sont tout-à-fait sous le domaine du système nerveux) en les contre-signant avec le nom de régulation centrale et de régulation périphérique.

Ceci, bien plus, est un système de compensation physiologique très important qui arrive pour faire acquérir à la température animale (dans les homéothermes) une moyenne constante.

La régulation automatique des vaisseaux influe indirectement sur la fonction des centres thermiques, pour l'influence qu'a sur la nutrition des mêmes.

Voici un lien nutritif entre régulation centrale et régulation périphérique; c'est le lien harmonique entre le système nerveux de la vie anormale et l'autre de la vie végétative. Mais il y a encore un autre lien, le fonctionnel.

C'est précisément ce lien là qui exerce l'écorce cérébrale avec son activité cortico-inhibitrice aux centres thermiques, basilaires, (ou thermogènes) et cortico-inhibitrice aux centres vasomoteurs.

Puisque les voies réfléchies des arcs diastaltiques thermiques doivent être tout-à-fait distinguées par les autres aussi réfléchies des arcs diastaltiques vasomoteurs corticaux. Tandis que les premières vont aux centres basilaires thermogènes, les autres vont aux centres vasomoteurs du bulbe et de la moelle épinière.

#### PLANCHE EXPLICATIVE DE TEL MÉCANISME.

Tous les deux systèmes d'arcs diastaltiques, quoiqu'ils aient tel lien intime, jouissent d'un automatisme fonctionnel dans le domaine de l'activité cortico-inhibitrice de l'écorce cérébrale.

C'est pour de tels mécanismes que la faculté d'équilibre entre la production thermique et la dispersion a des limites physiologiques très amples dans les animaux et plus encore dans l'homme, qui a le système de coordination le plus parfait, dans tous les mécanismes réfléchis ordonnés.

La planche V rend bien clair la dynamique de tels mécanismes. Il faut à la fois dire que chaque centre thermique (thermogène ou cortico-inhibitoire), comme tous les centres nerveux, est centre d'un arc diastaltique avec des voies incidentes et des voies réfléchies. Les incidents sont les thermo-sensitives et elles vont avec les voies de sens,\* les réfléchies sont bien distinguées, selon qu'on traite des centres thermo-inhibitoires corticaux, ou des centres inhibitoires corticaux aux vasomoteurs, ou après tout des centres thermogènes basilaires.

Les voies réfléchies de ces derniers ont été démontrées expérimentalement, tandis que les voies réfléchies aux centres de l'écorce cérébrale sont admises avec assuré jugement et sont les mêmes voies par lesquelles se transmet la inhibition des centres corticaux aux centres automatiques ordonnés mis dessous, savoir: les thermogènes basilaires et les vasomoteurs.

\* Ces voies de sens encore, comme les voies motrices ont la décussation dans les pyramides, et forment ainsi le croisement pyramidal supérieur de Meynert. Voir page 56 de ma publication, 1ère édition, 1891: "Se esistano centri termici e se esista una regolazione termica indipendente dal sistema vasomotore."

Pour tels mécanismes la production thermique est réglée par le système d'arcs diastaltiques thermiques, qui ont leur centre dans les cortico-inhibitoires thermiques et dans les thermogènes basilaires, tandis que la dispersion est réglée par l'autre système d'arcs diastaltiques, qui ont pour centres les cortico-inhibitoires aux vasomoteurs, les centres vasomoteurs et la série ordonnée de ces derniers. (Voyez planche V).

Les mécanismes de tous les deux régulations sont activés en conditions physiologiques par stimulus réfléchis constants.

#### ENCORE SUR LE MÉCANISME SUSDIT.

L'harmonie de la production thermique avec la dispersion physiologiquement subite des oscillations, qui trouvent leur interprétation dans la variabilité des stimulus de l'ambient externe (dans le sens le plus large du mot).

La régulation de la chaleur en conditions physiologiques ne pourrait s'activer sans les voies incidents et sans les stimulus du monde externe (dans le sens plus large du mot) sur telles voies.

La température des homéothermes subira des graves oscillations, ne garderait pas la température media physiologique constante à chaque ordre et classe. C'est pour ça que la nature a multiplié les voies incidentes\* sur les motrices (les réfléchies).

Il est bien clair, qu'il existe une apperception thermique liée aux activité cortico-thermo-sensorielles. Parce qu'étant le sensorium commun avisé de toutes les variations des stymulus périphériques (dans le sens plus large du mot) tout à la fois excités même les centres régulateurs du dynamique thermique, qui sont activés physiologiquement par excitation réfléchie et constante, car l'excitation authoethone, n'est pas le stimulus ordinaire.

Dans un champ si vaste de centres d'arcs diastaltiques, thermiques et vasomoteurs les stimulus authoethones ne peuvent être portés que par le plasma qui les arrose.

#### THÉORIE SUR LA FIÈVRE.

C'est pour ça que l'abnorme crasis du plasma, le chimisme altéré du plasma qui les arrose, vient traduit en faits de dynamique thermique altérés par imparfaite fonctionnalité de la série ordonnée des mécanismes thermiques et dispersifs.

Altérée de cette façon la nutrition de tels centres nerveux, l'organisme est en proie du procès fébrile.

La voici la cause unique productive du procès fébrile: C'est la crasis du plasma altérée pour changement chimico-moléculaire du même, qui influe directement sur la nourriture des centres des arcs diastaltiques thermiques et des arcs diastaltiques vasomoteurs.

En conséquence il y a la rupture des harmoniques rapportés (lien nutritif et fonctionnel sus-énoncé), par lesquels vient accomplir la fonction thermo-regulatrice physiologique.

Par l'altérée nourriture des centres des arcs diastaltiques susdits en suit une faiblesse dynamogène nerveuse, qui se traduit sensiblement en une moindre célérité de vibrations de l'éther nerveux.

La diminution de la quantité de mouvement de l'éther nerveux en telle rencontre est telle que ne peut pas modifier l'extension, la célérité, la direction des vibrations de l'éther, traduit sensiblement en chaleur par les activités chimiques des tissus.

Elle est parétique sans doute dans le système nerveux l'activité qui rend harmonieuse les vibrations de l'éther nerveux à l'état de vue des éléments cellulaires. Est-elle paréthique précisément l'activité apte à traduire la chaleur chimique en chaleur organique vitale, c'est-à-dire: "Telle qui ne puisse altérer la vie des protoplasmes cellulaires."

\* Les Physiologistes opinent que les fibres de sens soient presque deux fois autant que les fibres motrices. Voyez Paladino, 1885, Instit. Physiol. et des autres Traité de Physiologie.

L'organisme ainsi est en proie des activités chimiques, qui s'exagèrent même pour les changements chimiques moléculaires du plasma, qui influent à son tour sur la nourriture des autres protoplasmes cellulaires, en rendant anormale la nutrition, et en accélérant en plusieurs rencontres la totale désagrégation moléculaire.

La doctrine physio-pathologique de la fièvre, comme j'ai déjà publié depuis longtemps dans mes précédents ouvrages, doit être fondée sur l'altérée nourriture des centres de la série ordonnée des arcs diastaltiques thermiques et vasomoteurs pour l'altérée crasis du plasma, et en conséquence, sur l'altérée mécanique régulatrice thermique, rendue anormale dans les fonctionnements des deux mécanismes susdits: le central pour la production de la chaleur, et le périphérique pour la dispersion.

#### CENTRES THROPHIQUES.

Sur la question: Si les centres thermiques soient même centres throphiques, je crois pouvoir donner aussi des modestes résultats.

Les recherches expérimentales m'ont démontré que les animaux lésés en tels centres perdent du poids.

Ce fait, je l'avais déjà remarqué à page 53 de ma dernière publication.\*

Le lapin de l'expérience S (Série V), 4 Mars 1891, perdit en 10 jours 60 grammes de son poids, et la température fut toujours au-dessus de la normale.

Le lapin de l'expérience L (série V), 18 novembre 1891, perdit de poids après 11 jours de la lésion encéphalique 80 grammes, après 14 jours 180 grammes.

Donc une preuve presque directe pour inférer que les centres thermiques soient mêmes des centres throphiques.

Tout ceci est bien en harmonie avec les vues que nous avons déjà sur la nourriture de l'organisme. Il est bien connu que le mouvement thermique organique est lié intimement avec les acts nutritifs de l'organisme.

#### THÉORIE SUR L'INFLUENCE DU SYSTÈME NERVEUX SUR LA CHALEUR ORGANIQUE.

En ayant démontré que dans la régulation thermique le système nerveux n'agit pas en *loto*, mais par mécanismes réfléchis ordonnés, par centres thermiques et vasomoteurs, par centres et par voies spéciales, je dois conclure, quant à l'influence du système nerveux sur la production thermique, en opinant: que l'activité dynamogène nerveuse avec son mouvement vibratoire, modifie la célérité, l'extension, et la direction des vibrations de l'éther, mis en vibration par les actes chimico-biologiques, qui arrivent dans l'intime texture des tissus, avec phénomènes d'interférence de mouvement vibratoire, et avec modification dans la direction de la propagation de tel mouvement.

Le voici précisément dans la vie nutritive physiologique comment la chaleur chimique se traduit en chaleur organique vitale, c'est-à-dire en parfaite harmonie quant à son degré avec les conditions de vie des protoplasmes cellulaires.

Dans la vie nutritive pathologique, dans la fièvre, c'est-à-dire dans l'inanition pathologique désignée par des changements chimiques-moléculaires du plasma, la chaleur organique vitale, dans le sens susdit, se traduit en chaleur chimique, pour l'activité dynamogène affaiblie du système nerveux, ou mieux, pour la célérité vibratoire affaiblie de l'éther nerveux, qui pour cela n'a pas tout à fait la quantité de mouvement, telle qu'elle puisse modifier la célérité, l'extension et la direction des vibrations de l'éther, mis en vibration calorigène par les échanges chimico-biologiques des tissus.

Comme j'ai déjà précédemment publié, il serait bien banal de songer que les centres thermiques (les thermogènes basilaires) soient producteurs de la chaleur.

Celle-ci est produite dans l'organisme par actions chimiques qui se produisent dans l'intime texture des tissus.

\* Voir Monographie "Centri termici e centri vasomotori in ordine alla termodinamica, ecc., 1891. Tip. Salvati: 2<sup>a</sup> ediz.

Cette chaleur, ce mouvement vibratoire de l'éther, est modifié par l'activité dynamogène du système nerveux, par les vibrations de l'éther nerveux.

Les centres thermiques étant centres d'arc diastaltiques sont des voies de conduction des vibrations de l'éther nerveux.

Telles vibrations sont excitées par les stimulus du monde externe (dans le sens plus large du mot), qui agissent sur les extrémités des voies incidentes de la série ordonnée des arcs diastaltiques.

Les mêmes vibrations de l'éther nerveux se propagent ensuite du centre de l'arc diastaltique par la voie réfléchie, lorsque tels stimulus sont physiologiques, mais si au contraire ces stimulus sont anormaux, il se renverse la direction des vibrations de l'éther nerveux, il y a alors un transfert d'activité dynamogène, de la branche réfléchie dans les voies incidentes des arcs diastaltiques, et ainsi sont altérés les mécanismes ordonnés, par lesquels la vie s'explique.

#### RÉFUTATIONS DE QUELQUES EXPÉRIENCES DE HALE WHITE.

Je ne puis pas clore cet argument sans discourir d'une récente recherche d'Hale White publiée dans le *Journal of Physiology*, Vol. XII, Nov. 3 de 1891.

L'assemblée opine que la température des inguinées dans le lapin soit plus élevée que celle du rectum.

De ces résultats expérimentaux il infère des conclusions sur les ablations de l'écorce cérébrale, quant à l'influence de la même sur le rapport entre la température vitale et l'inguinale.

White expérimente ainsi : avec le même thermomètre mis dans le rectum, il passe à mesurer la température de l'inguinée. Il a remarqué dans cette rencontre que la colonne de mercure monte encore de quelque dixième pour 3 ou 4 minutes.

J'ai expérimenté même de cette façon, et d'avantage j'ai fait des autres recherches en observant la température avec des aiguilles et des sondes thermo-électriques, et j'ai eu des résultats opposés : la température anale a été toujours supérieure à l'inguinale.

C'est pour ça que je n'ai pu pas suivre White dans ses vues sur l'influence de l'écorce cérébrale.

#### EXPLICATION DE LA PLANCHE V.

M. C. Manteau cortical.

*g 5 h e g' 5 h'.* Symbolise le système des arcs diastaltiques vasomoteurs de la moelle et périphériques P.

La mécanique thermique régulatrice des conditions physiologiques s'accomplit par deux systèmes d'arcs diastaltiques séries entre eux: Les systèmes A et B par lesquels est accomplie la régulation centrale; et les systèmes C et D par lesquels est accomplie la régulation périphérique.

La mécanique des deux régulations est activée par stimulation réfléchie constante.

Tous les deux ont entre eux des liens intimes: Le nutritif et le fonctionnel. Tous les deux jouissent d'automatisme fonctionnel, sous le domaine de l'activité inhibitrice corticale. (V. 1<sup>a</sup> Monographie au titre "Centri Termici," juillet, 1890. Tip. Salvati, et les autres successives.)

## THE ABSORPTION OF IRON IN THE ANIMAL BODY.

By A. B. MACALLUM, M. D.,

*Professor of Physiology, University of Toronto.*

The author's observation on the distribution of iron in the animal and vegetable cell have resulted in determining that the chromatin of every species of cell is an iron-holding compound and that this substance gives origin to the hæmoglobin in the animal body. It follows from this that the iron of inorganic preparations in the food, if it is assimilated at all, must go directly to the formation, not of hæmoglobin, but of chromatin—a conclusion which necessitates a revision of the commonly accepted views as to the physiological relations of iron, and which at the same time suggests two interdependent questions: (1) Is chromatin formed in the animal body, or is it formed in vegetable organisms only? (2) What is the true explanation of the beneficial effects of the administration of iron salts?

In an attempt to answer these questions, various compounds of iron have been administered to animals (guinea pig, rabbit) in order to determine by micro-chemical and histological methods their action in the intestine. The investigation has yielded results which may be summarized thus:

(1) The chloride, phosphate, and sulphate of iron and certain organic preparations of iron are absorbed by the epithelial cells of the villi and by the siderophilous cells surrounding the lacteal vessels.

(2) When given in large doses, certain preparations of iron have, upon the absorbing elements, especially the siderophilous cells, an effect similar to chemotaxis.

(3) The absorption of iron compounds occurs chiefly in the upper and middle portions of the small intestine.

The beneficial effects of the administration of iron in anæmia may, in large part, be explained on the view that iron salts increase the absorptive activity of the intestinal mucosa. Other investigations on the absorption of chromatin tend to support this view and to indicate that inorganic and albuminate compounds of iron are not assimilated in the animal body, or, in other words, iron-holding nucleo-albumins are products of vegetable metabolism only.

The bearings of these observations on the pathology of simple anæmia and chlorosis and on the subject of nutrition is discussed at length in the original paper.

## ON THE PROTEOLYSIS OF CRYSTALLIZED PHYTO-GLOBULIN OR VITELLIN.\*

By Dr. R. H. CHITTENDEN.

The study of digestion is interesting and important in its chemical as well as in its purely physiological aspects. In the performance of the natural functions of the body these two phases are everywhere closely related. The phenomena to which each gives rise are dependent upon those of the other to a very great extent, and the normal or abnormal manifestation of the one series of actions always has a decidedly modifying influence upon the conditions of the other series. It is in its chemical aspects, however, that the basis of a correct interpretation of the digestive processes lies, and since proteid foods are essential to the very existence of the body the study of the chemical changes which these undergo in digestion is of great significance to the physiologist.

Considerable was known in a general way, previous to Meissner's work, regarding the greater solubility and diffusibility of the end products of proteolytic action; but this investigator and Brücke were the first to advance more definite views as to the nature and reactions of these products. Their opinions, however, differed somewhat; the discordance being often due doubtless to a difference in the artificial conditions of their experiments and in the interpretation of their results. The more recent discoveries pertaining to the proteoses and true peptone are especially responsible for the present theories of the chemical physiology of proteid digestion. At the present time the study of the cleavage products resulting from the action of the gastric and pancreatic proteolytic ferments has been extended so as to include practically all of the common forms of proteid matter. All of the results obtained lend favor to the theory that in digestive proteolysis the large proteid molecule undergoes a series of progressive changes, resulting in a cleavage into relatively smaller molecules, representing bodies more soluble and more diffusible; thus they better fulfill the physiological requirements of absorption and an example is afforded of how important a part chemical transformation plays in the functional activity of the system.

The advances in the methods of separating the individual albuminoses or proteoses have given an added impetus to the study of the products obtainable from different proteids, especially in view of the natural diversity of proteid food stuffs. The resulting proteoses and peptones, as might be anticipated from their varied origin, show some noticeable differences in their reactions, as well as in their composition, although certain marked characteristics are common to all of a given series. Blood-fibrin, myosin, paraglobulin, egg albumin, elastin, gelatin, casein, and gluten-casein have all been investigated, and their digestive products carefully examined. This, to be sure, has extended our knowledge of the individual proteoses and given us much valuable information, but in order to understand thoroughly the precise nature of the digestive processes we need to be very sure of the exact nature and chemical composition of the proteid undergoing digestion. In any exact study of the relationship between the various products resulting from ordinary proteolytic action and the mother proteid, the purity of the latter must first be assured. Obviously the colloidal or amorphous character of ordinary proteids is a great obstacle to chemical purity. In crystallized phyto-globulin, however, we have a form of proteid matter, the crystalline character of which offers a comparatively easy means of insuring reasonable purity. These crystalline proteids have, indeed, been known for a long time, and Neumeister,<sup>†</sup> as well as the writer,<sup>‡</sup> has previously

---

\* Abstract of a paper by R. H. Chittenden and L. B. Mendel.

† Ueber Vitellosen; Neumeister, Zeitschrift für Biologie, Band 23, p. 402.

‡ Crystalline globulin and globuloses or vitelloses. Chittenden & Hartwell, Journal of Physiology, vol. ii, p. 435.

reported on a few experiments designed to throw some light on the character of their digestive products. Hitherto, however, the great difficulty attending the preparation of large quantities of these crystalline proteids, and the somewhat vague ideas as to their nature, have constituted obstacles sufficiently great to interfere with their use in digestion experiments.

Within the last two years Osborne,\* making an extended study of the crystalline vegetable proteids, has called attention to the relative abundance of a beautifully crystallized globulin or vitellin in hemp seed. This proteid we have been able to isolate in a state of perfect purity in quantities sufficient for all practical purposes, and with this product have attempted a further study of the proteoses and peptones obtainable by the action of both pepsin and trypsin.

The hemp seed proteid crystallizes in the form of clean cut octahedra with some hexagonal plates. Under the microscope the crystals are seen to have as sharply defined edges as crystals of arsenious oxide freshly sublimed, thus showing the absence of amorphous impurities. It is a typical globulin, or phyto-vitellin, practically insoluble in water, but easily soluble in 10 per cent salt solution, especially when warm, and crystallizing readily from a hot saturated solution as the fluid cools. Further, when a salt solution of the proteid is dialyzed the vitellin frequently separates in crystalline form as the salt diffuses. In fact, it is a globulin exceedingly prone to crystallize, even under what might be termed unfavorable circumstances, a peculiarity which tends to give an assurance of purity. It is readily soluble in 0.2 per cent hydrochloric acid and in 0.5 per cent sodium carbonate, being readily converted, especially with the aid of heat, into acid albumin and alkali albumin, respectively. Like all globulins, it is more or less coagulable by heat, but is peculiar in that the coagulation point is exceedingly high; thus, a 10 per cent sodium chloride solution containing 0.5 per cent of the proteid does not show any signs of turbidity until a temperature of 79° C. is reached and flocks do not appear until the temperature rises to 91° C. Even then, and indeed on boiling the solution, coagulation is very incomplete. A quantitative experiment tried in this connection is interesting as showing how little confidence can be placed in separations made solely by heat precipitation. Thus, 10 grams of the pure crystallized proteid were dissolved in about a liter of 10 per cent salt solution and the fluid heated to boiling and kept at that temperature for thirty minutes. The flocculent coagulum resulting was filtered off, washed, and weighed. It amounted to just about 50 per cent of the original proteid. The filtrate from this heat-precipitate was then dialyzed until the greater portion of the salt was removed, when the remaining globulin separated out in the original crystalline form, thus showing that it had not been altered by the prolonged exposure to the high temperature. Again dissolved in salt solution and exposed to 100° C., another coagulum gradually formed; and doubtless if this process had been repeated a sufficient number of times the entire quantity of globulin would have been coagulated. Evidently, however, this vegetable globulin is very slowly coagulable by heat.

The composition of the crystallized proteid is much the same as that of the more frequently analyzed squash seed globulin, being especially characterized by a high content of nitrogen and a correspondingly lower content of carbon. Thus, the average composition of several distinct preparations shows 51.58 per cent of carbon, 6.88 per cent of hydrogen, 18.80 per cent of nitrogen, 1 per cent of sulphur, and 21.65 per cent of oxygen.

Like all proteid bodies, this phyto-vitellin is laevorotary; dissolved in 10 per cent salt solution it has a specific rotation of  $\frac{a}{D} = -53.8^\circ$ . Haas has determined the specific rotation of serum globulin to be  $-59.7^\circ$ . Dissolved in 0.2 per cent hydrochloric acid, the proteid is readily attacked by pepsin, and is gradually transformed into proteoses and peptone, while a small amount is simultaneously converted into an

\*American Chem. Journal, vol. 14, p. 675.

insoluble anti-albumid-like body, which may be appropriately termed anti-vitellid. It is needless to say that in these digestion experiments the pepsin employed was a carefully purified preparation of the ferment, as free as possible from all traces of adhering albumoses, etc. It is unnecessary to weary you with details of separation and methods of purification; suffice it to say that two pepsin digestions on a large scale were carried out, 150 grams of the pure crystallized proteid being used in each digestion. In the first experiment the mixture of proteid, pepsin and hydrochloric acid was warmed at 40° for seventy-two hours. In the second digestion, a somewhat stronger pepsin solution was employed and the mixture was kept at 40° C. for ten days. The first point to be noticed in the results obtained is the relative formation of proteoses and peptone under these somewhat widely divergent conditions. The accompanying table brings out the differences with sufficient clearness:

| Digestion.      | 72 hours.        | 10 days.         |
|-----------------|------------------|------------------|
|                 | <i>Per cent.</i> | <i>Per cent.</i> |
| Vitelloses..... | 36               | 33               |
| Peptone .....   | 63               | 66               |
| Vitellid .....  | 1                | 1                |

These figures are to be considered simply as an approximation merely, since considerable loss naturally occurs in the separations. They illustrate, however, a feature of gastric digestion which I think has been already clearly demonstrated with other proteids, both in natural and artificial digestions, viz, that under no ordinary circumstances do we have a complete conversion of the proteid undergoing digestion into peptone. There always remain a residue of proteoses, which are very slow to undergo further transformation into peptone, even though the period of digestion be greatly lengthened or the strength of the ferment solution be greatly increased. The initial action may be rapid up to a certain point, beyond which further conversion into true peptone is slow and finally comes to almost a complete standstill. Thus, in the two experiments above quoted continuation of the digestion for ten days resulted only in the formation of 3 per cent more peptone than in the shorter digestion of seventy-two hours. It must not be assumed, however, from these figures that the ferment was wholly inactive during the greater portion of this second digestion period. This certainly was not the case, for analysis of the proteoses obtained from the two digestions shows plainly that in the longer and more active digestion the proteoses are represented by a far larger percentage of secondary proteose, the primary products being correspondingly diminished in amount. This is clearly shown in the following table:

| Digestion.                                          | 72 hours.           | 10 days.            |
|-----------------------------------------------------|---------------------|---------------------|
|                                                     | <i>85 Per cent.</i> | <i>21 Per cent.</i> |
| Proto-vitellose.....                                | 35                  | 21                  |
| Hetero-vitellose.....                               | 2                   | 1                   |
| Mixed vitelloses (CH <sub>3</sub> -COOH p. p.)..... | 47                  | 49                  |
| Deutero-vitellose.....                              | 16                  | 29                  |
| Total .....                                         | 100                 | 100                 |

These results, then, are fully in accord with the view that in digestive proteolysis we have to deal with a series of progressive changes resulting in the formation of a series of soluble and diffusible bodies known collectively as proteoses and peptones. Hitherto we have been wont to limit our ideas of the proteoses to the primary bodies proto- and hetero-proteose and the secondary proteose, known as deutero-proteose, each of these being considered as existent in both the hemi and anti form. A fourth body, known as dysproteose, is simply a coagulated form of hetero-proteose. The writer, however, has had for some time a growing conviction, based upon the

many results obtained in this field of work, that digestive proteolysis is still more complex than we have been wont to consider it. The proteoses may, perhaps, be compared to the many more or less isomeric dextrans formed in amylolytic digestion, a given proteose, for example, being considered not necessarily as a single substance but rather as a representative of a group of closely allied bodies representing different stages in the proteolysis. We have been led to consider the possibility of this view because of the apparent lack of agreement oftentimes noticed in the composition of a given proteose when repeatedly separated from different digestive mixtures. In other words, the composition of a given proteose appears to vary more or less with variations in the extent of the proteolytic change by which it has resulted; that is to say, the length and intensity of proteolytic action appear to exert a modifying influence upon the composition of the resultant proteoses. It was especially to test this point that the present experiments with pure crystallized phyto-vitellin were undertaken. In proteolytic digestion it has always been noticed when careful analyses of the products have been made that the proteid undergoing digestion loses carbon as the hydrolytic change proceeds, so that each successive product of proteolysis contains less carbon than its direct antecedent down to true peptone, the final product of gastric digestion, which latter body may contain two-fifths per cent less carbon than the mother proteid. Thus proto- and hetero-proteoses, as primary products, contain, as a rule, only a little less carbon than the proteid from which they are derived; while deutero-proteose, a secondary product of hydration, always contains still less carbon; and true peptone, the final product of the hydrolytic change, a still smaller amount. Now, whatever the conditions under which these several bodies are formed their general characters are always the same; their chemical reactions and general properties, so far as we are able to recognize them, are always essentially constant; but their chemical composition shows marked variation. Further, this variation is something more than a mere variation such as might be attributed to lack of complete purification, etc. It is a variation which shows a certain degree of constancy, pointing in a certain direction, and, if the results are to be trusted, indicates that the composition of a given proteose, as now defined, is variable within certain limits, the exact composition being dependent upon the length and intensity of the proteolytic action. This point is well illustrated by the present series of experiments. Thus, in the two digestions already described, both conducted under exactly the same conditions, excepting that one was continued for seventy-two hours and the other for ten days, and the latter with a somewhat stronger pepsin solution, proteoses of essentially the same general character were separated, but with the following variations in composition:

|                                           | C.    | H.   | N.    | S.   | O.    |
|-------------------------------------------|-------|------|-------|------|-------|
| Vitellin .....                            | 51.63 | 6.90 | 18.78 | .90  | 21.79 |
| Proto-vitellose, first digestion .....    | 51.55 | 6.73 | 18.90 | 1.09 | 21.73 |
| Proto-vitellose, second digestion .....   | 50.45 | 6.68 | 17.10 | 1.28 | 24.49 |
| Mixed vitelloses, first digestion .....   | 50.85 | 6.68 | 18.94 | 1.10 | 22.43 |
| Mixed vitelloses, second digestion .....  | 49.43 | 6.77 | 18.37 | 1.29 | 24.14 |
| Deutero-vitellose, first digestion .....  | 49.73 | 6.73 | 17.97 | 1.08 | 24.44 |
| Deutero-vitellose, second digestion ..... | 50.03 | 6.70 | 18.93 | 1.53 | 22.81 |
| Peptone .....                             | 49.40 | 6.77 | 18.40 | .49  | 24.94 |

If this was the only series of results of this nature that we had to offer I should hardly think it worthy of calling attention to, but results along the same general line have been cropping out continually and to my mind they have some significance. Thus, the proto-vitellose separated from the two digestions shows a variation of 1 per cent of carbon, and it is to be noticed that the lower content of carbon belongs to the body resulting after ten days' digestion at 40°. C. Further, with the mixed proteoses, the acetic acid precipitate, or a mixture of proto- and deutero-vitellose, the same result is to be noticed. Further, in both instances the nitrogen likewise shows a diminution as an apparent result of the longer proteolytic action.

With deutero-vitellose and true peptone the final products of the proteolytic change there is less tendency for this variation in composition; it is usually more apparent in the primary proteoses.

I am well aware that these results are open to criticism; that it may be said they are the result of mere accident; that if they imply anything they testify simply to the general lack of definiteness of this class of bodies. But to this I answer that it is comparatively easy to obtain these bodies with like composition over and over again by simply keeping the conditions under which they are formed fairly constant. It is only when the conditions are changed; when the first-formed bodies are exposed to renewed ferment action that changes in their composition begin to appear, although the general characters of the bodies, the reactions on which their identification and separation depend, remain constant. Other forms of proteid matter have given these results and, now that they are likewise obtained with this, a purer form of proteid matter, we are convinced that they have some real significance, a significance that may be interpreted as furnishing additional evidence that the proteolytic process considered from the chemical standpoint is one of gradual, successive changes, resulting not only in the formation of a series of well-defined bodies such as the proteoses and peptone; but that these, especially the primary proteoses, may be represented by a class of semi-isomeric bodies showing only slight shades of difference yet each standing for a definite step in the proteolytic process.

---

#### CHANGES IN GANGLION CELLS FROM BIRTH TO DEATH FROM OLD AGE; PRELIMINARY COMMUNICATION.

By C. F. HODGE, Ph. D.,

*Assistant Professor of Physiology and Neurology, Clark University.*

Whatever may be true of the protozoa and certain of the lower metazoa, which multiply by fission, undoubtedly for all higher animals the process of growing old, of senescence, is a normal physiological process. It is manifested, probably, in all tissues, from the bones, which lose their animal matter; the muscles, which waste away; and the glands, which sclerose, to the brain, which becomes enfeebled, incapable of thought or will. Dr. Holmes may take exception to this last statement, and he has good right to; but for the general run of old men and old dogs that can not learn new tricks the above holds true. In fact, it is such shining examples as the one just named that urge to a physiological study of ageing that all may grow old as gracefully as Dr. Holmes.

Search should be made through all the tissues for the cause of somatic death. This cause may lie equally in blood, muscle, gland, and nerve; and the intricate interdependence of organs and functions which constitute the circle of an animal's life would support this view. My own previous work makes it expedient for me to begin the search with the nerve cell; and besides, there are reasons for believing that this element plays a preëminent rôle in the determination of somatic life. It is true, muscle and nerve are often referred to as "master tissues" of the body. But muscle is certainly a poor sort of a slave to be called a master. Whenever bidden by a nerve impulse, it contracts. Otherwise it lies quiescent and fails even to nourish itself, shriveling in atrophy if cut off from its nerve supply. The relation of gland to nerve is in general similar; and thus the nervous system may indirectly determine the nutritive constituents of blood and lymph. It is a remarkable and significant fact in this connection that in the embryo the nervous system develops so far in advance of the other organs, and that a lesion here during embryonic life so often causes arrest of growth in corresponding parts of the body. It is not the place, however, to discuss the trophic influence of nerve centers.

In speaking of normal death and in searching among the cells of the various tissues for its cause, I refer, of course, to theoretically physiological dying. Where death is complicated with disease of kidney, or lung, or heart, examination is made of these organs and their pathology gives us the cause of death. Even here, it should be remarked aside, the real cause often lies behind the organ itself in the nerve centers which furnish it control. With man the process of physiological decline often reaches the stage of senescence, but rarely the point of actual death. The fact that it is a normal process renders search for its cause none the less legitimate and only enhances its scientific significance and interest.

The above may serve to indicate the point of view from which I have undertaken a study of the problem. The present paper can only be put forward as a preliminary communication, embodying a year's work in a field to properly cover which must require the united efforts of a number of workers for many years. At any rate a sufficient number of animals should be studied, in all tissues, to enable us to distinguish special from general results.

Changes in the walls of the blood vessels within the brain and spinal cord of the aged, as well as sclerosis of the nerve tissue itself, have already been described. Although related, these are aside from my present purpose, which is to confine attention entirely to intracellular phenomena. The exact question is, What differences in the cells themselves can be discovered by comparison of similar nerve cells from the young and the old? In this field Schultze\* has attempted to prove that pigmentation of ganglion cells increases with age, and this has been associated with pathological pigmentary degeneration. Schäfer† opposes the idea of any such connection, maintaining that pigment everywhere in the body is evidence of functional activity and not of decay.

Observations which I wish to report at this time have been made upon the following material:

First, the cerebrum, cerebellum, cervical cord, and first cervical ganglia of a man dying of old age at 92 years. So far as could be observed or ascertained, cause of death was not complicated with disease of any sort. During the last two years he came gradually to require more and more sleep, considerably more in winter than in summer. At last it became difficult to awaken him for meals. Finally this became impossible and after six days of inanition respiration and pulse grew weaker and weaker and finally ceased without the slightest struggle or even movement to mark the point of death. The above-named parts were removed 11 hours post mortem, and were prepared by methods to be presently indicated.

Second, the first cervical ganglia of a male foetus killed by accident of birth.

Third, portions of cerebrum, cerebellum, and first cervical ganglia of a man killed by accident at the age of 47.

Fourth, superoesophageal ganglia of 21 old honey bees prepared side by side with brains of the same number of young bees taken as they emerged from the brood cells.

In the human cerebrum at 92 years of age no pronounced abnormality has been detected by methods thus far employed. By the osmic acid-bichromate method of Ramón y Cajal, both as to size of cell and number of processes, neurons, and dendrons, everything appears normal. The alcohol-magenta, mercuric chloride, and long osmic acid methods show usual appearance of protoplasm, with considerable pigment, nuclei full and clear and nucleoli prominent. If degenerative changes are present, they do not involve a sufficiently large proportion of cells to strike one in the ordinary study of the sections. The cells of Purkinje appear considerably shrunken, both nucleus and protoplasm; though not more so than in normal daily fatigue. There are also 25 per cent fewer, by count, than in sections of cerebellum of the middle-aged man, cut at the same stroke of the knife. This difference may

\* R. Schultze. Ueber Artificielle, Cadaveröse und Pathologische Veränderungen des Rückenmarks. Neurol. Centralbl. Bel. II, S. 529-536, 1883.

† Schäfer. The Nerve Cell as a Basis of Neurology; Brain, 1893.

not be abnormal. Most striking differences occur in the cells of the spinal ganglia. Possibly the most important of these is a failure of the nucleolus to stain with osmic acid in cells of the old man. Considering the rôle which this organ plays in processes of reproduction, and it possibly plays no less a rôle in subsequent physiological functions, this fact may have a wide significance. Coupled with this is the condition of the nucleus, considerably shrunken and with irregular, jagged outline. In case of fatigue the nucleus shrinks and at the same time grows dark. In the old-age specimens the nucleus has shrunken and remains light, not taking the stain more heavily than the cell protoplasm. Nucleoli are large and densely stained in corresponding cells of the fœtus, and nuclei are large, round, and clear, not a single one being at all shrunken or dark. Camera drawings of the two are shown in figs. 1 and 2. The protoplasm in the old man is seen to be largely filled with pigment and fat, both substances appearing black in osmic acid specimens, the pigment being yellow and the fatty masses being represented by large vacuoles in sections by the corrosive sublimate method. The cells of the fœtus contain almost no pigment at all.

The above comparison may best be expressed in tabular form as follows:

TABLE I.

|               | Volume of<br>nucleus. | Nucleoli<br>observable<br>in nuclei. | Pigment,<br>much. | Pigment,<br>little. |
|---------------|-----------------------|--------------------------------------|-------------------|---------------------|
|               | <i>Per cent.</i>      | <i>Per cent.</i>                     | <i>Per cent.</i>  | <i>Per cent.</i>    |
| Fœtus .....   | 100                   | In 53                                | .....             | .....               |
| Old man ..... | 64.2                  | In 5                                 | 67                | 33                  |

It was not found possible to gain much light upon exactly the point in question from the brain of the man killed by accident. This was a disappointment; since it was hoped that it might furnish a specimen of human brain in prime of life not complicated by pathological conditions, something quite difficult to obtain. The man was, however, a confirmed alcoholic, and by the osmic acid method, upon results of which my comparisons were in the main founded, fully nine-tenths of the ganglion cells in cerebrum and spinal ganglia stained as black as fat cells, showing no structure whatever. Whether the alcohol habit has anything to do with this result remains for further experiment to decide. The rest of the cells stained darkly and were considerably filled with pigment and fat, but showed large, clear nuclei and normal nucleoli.

With the honey bee, experiments could be far better controlled, and results are accordingly more definite. The young bees were caught in the act of crawling out of the brood cells. They are at this time practically ready to begin their life work. The fact that in all cases the honey sac was found moderately distended with honey will serve to indicate a uniform nutritive condition. Old bees were chosen by "age signs," worn and frayed wings, abraded hairs, and general behavior. This last was of special use. When a hive is opened, all the able-bodied bees are alert and active in protecting the combs or in securing what honey each can carry. Here and there, generally off in some corner, you may observe a bee quietly humped up, taking neither part nor interest in the general commotion. Such a one is likely to bear the signs of extreme age. The experiments were made in August during a period of honey dearth, while the bees were "loafing," in order to obtain results as free as possible from complications with fatigue. This matter will require consideration further on. The young and old bees were beheaded, the front and side portions of the skull quickly pared away with a sharp scalpel so as to expose the brain, and both were placed in the same watch glass of 1 per cent osmic acid for two hours. From this they passed, with the old and young always in the same bottles or dishes, through the usual steps to hard paraffin, where young and old were cut side by side with the same stroke of the section knife. In no case were specimens to be compared separated in passing from the living bee to the microscope slide. While paring off the

skull caps I was struck by a remarkable difference in size between young and old brains. The young brains fill the skull so full that it is difficult to lift off the chitin without injuring the parts below. The old brains are shrunken into a flat cake filling not half the cavity of the skull. It is easy to observe this with the unaided eye. Reasons for the above will appear when examination is made of the sections. These were cut with a Minot microtome, new model, 2 and 6  $\mu$  thick. Sections of the 21 young brains appeared under the microscope as much alike as though they had been successive sections cut from the same brain. The nuclei are large and clear. They are, in fact, so large in proportion to size of cells that they often crowd one another into polyhedral shapes. This is shown in fig. 3, drawn from the antennal lobe of young bee No. 1. Protoplasm appears dense and evenly granular. In the old brains protoplasm is all but absent, being reduced to a few shreds and granules between the large vacuoles which fill the cell. The nuclei are shriveled in many cases almost beyond recognition. Here, too, as we found in the human ganglion cells, the nuclei in senescence decrease in size, but do not grow dark and granular as in fatigue. This general result is not so uniform for old as for young brains, and naturally so; because it is of course impossible to obtain old bees of uniform age. The age signs by which they were chosen are no more uniform than the appearance of the brains. The above description applies literally to the extreme cases; and not one of the old brains failed to show differences of the character indicated by which they could easily be distinguished from young brains. (Compare figs. 3 and 4.)

In addition to the above, the most noteworthy result furnished by the bees is that the cells are much more numerous in the young than in the old. A count of 22 groups of cells taken as nearly alike as possible in old and young give an average of 1 cell in the old to 2.9 cells in the young. In all cases the cells were fewer in the old. In a former series of experiments \* bees were killed morning and night, in order to demonstrate, if possible, changes in brain cells owing to fatigue of a day's work. Differences in appearance of cells were found which could not be accounted for on grounds of daily fatigue, and it was then urged (p. 155) that the only variable which could account for them must be a difference in age. The present series confirms that opinion so strongly that in future no study of nerve-cell fatigue can be considered final until just allowance has been made for differences due to age. Daily fatigue in bees must be worked over again with this point in view; and just how far results as obtained in diurnal fatigue of birds may have been complicated by age can only be determined when changes due to aging have been studied in some one, at least, of this class. This brings us back to our first experiments, in which corresponding cells of the same animal were compared. Here no complication of age can have influenced results. It was demonstrated that in fatigue the cell protoplasm became vacuolated, the nucleus shrunken and came to stain more darkly, and the nucleolus showed a tendency to decrease in size, although this is not constant. Testimony from all sides points to the nucleolus and nucleus as the source of origin of the protoplasm. In extreme age we find protoplasm vacuolated in bees, pigmented in man, nucleus shrunken, but not dense, as in fatigue, and the nucleolus absent from a large proportion of cells in man. The nerve cells of the honey bee do not possess a sharply defined nucleolus like that of vertebrates. If anything of the kind exists in these cells, it must be represented by irregular granules, as indicated in fig. 3. These, as may be seen in fig. 4, are largely absent from nuclei of aged cells.

The nucleus being the source of rejuvenation for the cell protoplasm, the above would seem to indicate that age is of the nature of final fatigue, final, because the source of energy for the nerve cell has dried up at the fountain head. Decrease in number would intimate that the young bee commences active life with a full quota of nerve cells. Filling the skull as they do, it is difficult to conceive, since the

\* Hodge. A Microscopical Study of Changes due to Functional Activity in Nerve Cells. *Journal of Morphology*, Vol. VII, Boston, 1892.

adult bee does not moult, how these cells can increase much in either size or number in subsequent life. To start with there is, in brief, a superabundance of cells which furnish the animal not only energy to maintain vital processes necessary to life, but in addition to this, energy for the performance of work. As the work of life is being performed, the cells, one by one, are worn out. A stage is reached when only enough cells remain to barely support processes requisite for continuance of life, no extra work being possible. Finally this number fails, and the functions of life must cease.

In the above I do not wish to be understood to insist that nerve tissue is of any more importance in relation to physiological dying than any other tissue. Just the position held by each tissue in this regard must clearly be determined by experiment.

The working out of age changes in the tissues of a series of animals is something which clearly requires, above all things, time for its consummation. The above is put forward in the hope that valuable material which might otherwise go to waste may be utilized in this connection. (Illustrations not furnished.)

## A MICROSCOPICAL STUDY OF THE NERVE CELL DURING STIMULATION.

By C. F. HODGE, Ph. D.

### EXPERIMENTS ON SPINAL AND SYMPATHETIC GANGLION CELLS OF FROGS.

The purpose of the present series of experiments is to observe continuously the process of fatigue in the nerve cell. Up to the present series my method has consisted in studying the cells at the end of a period of fatigue and only after the tissue had passed through the usual processes of preparation for the microscope. From the first it has been my desire to study the process continuously in the living cell. A report of former work upon the subject of changes in ganglion cells due to electrical stimulation and daily fatigue may be found in a previous number of the *Journal of Morphology*.\*

#### *Method.*

At first an attempt was made to observe the cells in situ with circulation disturbed as little as possible. This was done by removing the viscera from in front and a portion of the spinal column, muscles, etc., from the back, tying all blood vessels, thus leaving the pleuro-peritoneum with its blood vessels and the sympathetic chain intact. Small frogs were used, but the large pigment cells in the pleuro-peritoneum itself, and especially along the blood vessels and sympathetic cord, made it impossible to get a clear view of the sympathetic ganglion cells. I was obliged to abandon the method. It thus became necessary to remove the ganglia from the body and free them from their pigmented capsules. In consequence of this the following method was adopted, and it has proved more serviceable than was anticipated. Special apparatus employed can best be understood in connection with a typical experiment. A pair of spinal or sympathetic ganglia is quickly excised from a freshly pithed frog. Each of these is placed immediately in a drop of normal salt solution on a "stage-electrode" of the following construction (fig. 1): A plate of thin clear glass (A), of shape indicated in figure and of a size to be conveniently clipped to stage of a Zeiss microscope stand, larger size, has two grooves cut in its under surface from margin to near center. These are made deep enough to conceal two fine platinum wires, which are cemented in them (B). A half centimeter beyond central

FIG. 1.—Microscope stage electrode.

- A. Glass plate.
- B. Two platinum wires laid in grooves on under side of plate and rising through plate to be exposed on upper surface to serve as stimulating tips at—
- C. Exposed portion of electrodes.
- D. Platinum wires to support cover slip.
- E. Wires to induction coil.
- F. Trough ground in glass plate to carry off stream of normal solution.

FIG. 2.—Setting of apparatus for ganglion cell stimulation.

1. Flask of normal solution.
- 2, 2'. Glass siphons which lead solution to edge of cover slip.
- 3, 3'. Beaker to catch drip.
- 4, 4'. Stage electrodes in position.
5. Drawing stand to hold card at level of stage.
6. Wires from right-hand microscope to secondary coil.

end of grooves the platinum wires are brought to upper surface of glass through two needle holes about 2 millimeters apart. The ends of the wires are then bent down into needle-hole pits in the upper surface of the plate about 2 millimeters beyond the first perforations. Shallow grooves in the upper surface are made to connect the holes of each pair, so that the platinum wires come to lie half exposed on the upper surface of plate for a distance of 2 millimeters (C). They are then filed off level with surface of glass. This portion of the wires, of course, acts as the electrode, and the preparation is arranged so that either the ganglion lies between the electrodes or its nerve lies over them. The other end of each platinum wire is soldered to an insulated copper wire, which goes to a secondary coil. Two other platinum wires (D) support the cover slip. These, for convenience, are hooked into pits in the glass, and are so bent and adjusted as to direct the stream of normal salt solution over the specimen.

With the plan of this simple electrode understood, the remainder of the method may be seen at a glance at fig. 2. Each electrode is clipped to its microscope and a stream of normal salt solution is drawn from flask (a) by means of glass siphons (b and b), which end in finely drawn nozzles. These are placed at edge of cover slip opposite trough (F), fig. 1. The stream from (F) drips into beaker (c). Other parts of figure need no explanation. We now have, living in the same fluid, corresponding ganglia of the same animal. A group of cells as nearly alike as possible is sought out in each preparation and brought to center of field. A cell, or several cells in each, are measured and outlined with aid of camera, and then electrical stimulation is applied to one of the preparations and not to the other. Both are watched and at intervals measured and drawn. Two cameras, each attached to its microscope, were used at first (as shown in fig. 2). To render the two pictures more comparable, avoiding thus any difference in the angle of the mirrors, a camera was clamped to the eyepiece, with mirror firmly set, and eyepiece and camera were lifted together from one microscope to the other. Stimulation was interrupted, fifteen seconds' work alternating with forty-five seconds' rest, the primary circuit current being made and broken by a "Lombard clock interrupter." Four Daniel cells, supplying current of .2 ampere, were used throughout. The induction coil used was one of Krüger's (10305 U). Aside from the electrode and device for supply of normal salt solution, the apparatus was made as similar as possible to that used in my earlier experiments and fully described in the paper just cited. At end of desired time both control and stimulated ganglia were placed together in osmic acid and teased in glycerin for further study and preservation.

In all, 33 experiments have been made. These have varied in duration from fifteen minutes to six days. They were divided into a winter series, made between November 25, 1892, and December 24, and a summer series, made from June 14 to September 3, 1893. Since no marked difference in results has borne out this division, I have substituted for it a grouping of the experiments according to their purpose and nature. It is intended to give in the following table a condensed statement of the whole research. Each experiment bears its date, but for convenience of reference the numbers have been given to the experiments as they stand in the table. The time of day is written as an exponent of the date, and since all experiments were made during daytime, no designation of "A. M." or "P. M." is required. As in the previous work, interest centers chiefly about the nucleus. Change in this is expressed in percentage of loss or gain, using the original volume as 100 per cent. Time in hours and minutes from beginning of experiments is written as an exponent of the shrinkage per cent. Where several cells were watched, each bears its proper number throughout the experiment. Controls enter the table only in case some change is noted in them. No significant change in size of cell body was observed, hence their omission from table. Experiments 1 and 2 were made with cells of sympathetic ganglia. In all the rest the spinal ganglia were used.

Table of all experiments.

| No. | Date.             | Position of coil. | Normal solution used. | Shrinkage in volume of nucleus.                                                                                                                                                                                                                                                                                                 |
|-----|-------------------|-------------------|-----------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|     |                   | <i>cm.</i>        |                       |                                                                                                                                                                                                                                                                                                                                 |

No nuclei or nucleoli visible in any of the cells, although they appear clear and free from pigment. Stimulation applied and in 20 minutes faint outline of nuclei became visible. After 4 hours and 30 minutes stimulation, faint irregular outline of nuclei visible. No nucleoli to be seen. |

FIG. 3.—Curves showing shrinkage of nuclei in experiments 18 to 21.

The most striking feature of the table is perhaps its great irregularity, the lack of any apparent relation between amount, duration or intensity of stimulation, and effect in change of nucleus. This is in apparent disagreement with results of former work, in which a quantitative relation between stimulus and shrinkage of nucleus was evident. It is, however, easy to show that the lack of agreement is only apparent. In the former experiments we were dealing with definite amounts of stimulus given in the same way to corresponding nerves, which in turn led the stimulus to corresponding ganglion cells. The point to be emphasized is that the cells were in position in the body under practically the same conditions of blood supply and nutrition and in similar relation to the stimulus. In the present series the cells are removed from the body, placed in a stream of solution, which it is impossible to make equal to the different cells, and in an electric field, the intensity of which in any point it is impossible to regulate or even estimate. Taking these important variables into account, the evidence for quantitative relations between stimulus and effect is, possibly, as strong as we should expect to find it. The measurements from which the percentages in the table were computed were made long and short diameters of nucleus as usual, with no thought beyond accuracy of each measurement. Differences and similarities between different experiments may be seen more clearly by plotting the percentages in the table in the form of curves. This was done for all the experiments. Four of the most comparable of the curves are reproduced in fig. 3, drawn from experiment 18 in 21 minutes. Position of coil and solution are the same in these experiments, yet the course run by each in its fatigue is distinct, though similar in character. By far the majority of the curves are of the same general form. They show that the cell tires rapidly at first, then more gradually to a condition of fatigue, complete, at least, so far as our present method is able to indicate. This is also in apparent variance with curves derived from a former series of experiments, in which fatigue was rapid at first, then gradual, then more rapid again. A slight tendency to this form of curve is found in experiments 6, 8, 9, 18, these all showing slight secondary acceleration. Considering the circumstances of the two series of experiments, no correspondence can be expected. In the present series the cells are not living in a nutrient solution, but in a normal non-nutrient solution, which is able, in all probability, to carry off by diffusion the waste matters of the cell's metabolism. Consequently the nucleus shrinks more rapidly and also more continuously to a condition of complete fatigue. As more fully discussed in a previous paper, there are reasons for believing that cells in presence of nutriment carry on the processes of anabolism and katabolism at the same time. Under the conditions of our present experiments, anabolism is impossible, while katabolism is, possibly, unimpeded or accelerated. Note the slight shrinkage which occurs in a few of the control ganglia.

Shrinkage in nuclei of control cells probably occurred to a slight degree in all experiments where simple sodium chloride solution was used. It never reached the point at which the nucleus began to show indentations. In Ringer's solution, or in salt solution saturated with calcium phosphate, no change in this respect could be detected, even for long periods. This agrees in the main with recent work by Locke\* upon the influence of so-called "normal" solutions on the form of curve of muscle contraction, salt solution making the curve higher than normal. A slight effect tending toward that produced by stimulation is no more than we should expect in transferring ganglion cells from blood to any normal solution. In experiment 9 the control nucleus takes a peculiar course. It is seen to swell slightly for the first two hours, then comes back to normal and continues to shrink, until in seven hours it has lost 19 per cent of its original bulk. I have, as yet, no adequate explanation for this case. It stands alone, so far as my observations go. Upon diluting a normal solution with distilled water, I have observed similar swelling of nuclei. This fact, however, throws little light on the present instance.

\*Locke, Die Wirkung der Physiologischen Kochsalzlösung auf querges treifte Muskeln, Pflüger's Archiv., Bd. LIV, S., 501-524, Bonn, 1893.

Experiments 1 to 23 were all made with the single purpose of observing changes which might occur in ganglion cells during stimulation. But few in this group require fuller statement than is already given in the table.

In experiment 3 the cells were kept under observation, at intervals, for six days. Camera drawings were made, at least one a day, during the whole time. Measurements were taken to begin with, and at the end of three hours. As the mirror of camera was moved, it is not possible to compute volumes accurately beyond this time. Measurements were omitted under the impression that camera drawings would serve instead. This necessitates a brief description by way of supplementing the table. The experiment was begun at noon, December 7, and during the first five hours the nuclei decreased in size and became irregular in outline. By the next morning, the nuclei had somewhat regained their rounded outline, though remaining small, and the appearance of both protoplasm and nuclei showed little or no change beyond the retraction of the protoplasm from capsule to closely envelope the nuclei. During the fourth day granules in protoplasm and nuclei appeared to be in violent commotion. My notes for this day contain the words, "cells alive with bacteria." An incrustation of salt had formed around edges of cover slip, in places. In washing this off with distilled water, a little ran under the cover slip, and the nuclei were observed to swell. It was expected that the "bacteria" would leave little of the cells to be seen next day. On the contrary, by the morning of the fifth day, all movement of granules had subsided and nuclei and protoplasm had regained, to all appearances, their former condition. Upon the morning of the sixth day, however, the nucleoli of two of the cells had entirely disappeared, and the outline of the nuclei in these cells could scarcely be distinguished. In the third cell the nucleus was visible, though faintly, and contained a small speck of still highly refractive nucleolus matter. On tapping the cover slip lightly to dislodge a mass of debris which had floated out so as to obscure some of the cells, they all flew to pieces and the experiment was at an end.

Experiment 4 also deserves a word of explanation. An attempt was made in this case to obtain, by showing the secondary coil to O, the greatest possible effect in the shortest time. Contrary to expectation, however, no change could be observed at first. Very little occurred during the first three hours, and the nuclei remained round and clear during nearly twenty-one hours of this extreme stimulation. Three more experiments, not given place in the table, were tried with coil in same position and with the same result. Motile protozoa were next submitted to the same stimulation. Paramecia were found to be killed almost instantly. At least they showed no signs of movement after a few, less than fifteen, seconds' exposure to the current, and speedily disintegrated. Large vorticellæ were able to endure more; but after two or three exposures of fifteen seconds each, they invariably succumbed. A number of similar tests were made with gradually decreasing strengths of current, and it was found that with the secondary coil at 10, paramecia, although considerably startled, did not appear to be injured. No relation necessarily exists between strength of current injurious to paramecia and to frog's spinal ganglion cells; however, 10 centimeters was decided upon as the limit of stimulation for remaining experiments.

Experiments 12 and 13 are anomalous. In perfectly clear unpigmented ganglion cells no nucleus or nucleolus is to be seen. This is not peculiar to the June experiments, for even during the winter several cases of the kind occurred. They were, at the time, discarded with the note, "cells not clear, no nuclei visible." The two instances, 12 and 13, are too pronounced to leave unrecorded. They force upon one comparison with the apparently similar disappearance of the germinal vesicle in the ovum at maturation. The fact that on stimulation traces of nuclei but none of nucleoli became visible, is also of significance. But whatever this may be, is at present a matter for experiment rather than discussion. In subsequent experiments, 14 to 33, made upon young frogs, *R. temporaria*, which had just passed the tadpole stage, left nothing to be desired in way of clearness of nuclei.

FIG. 5.—Camera outlines of changes in nucleolus in experiment 31 during 22 minutes stimulation in 0.1 of potassium tartrate added to normal solution, a—c occurred in 4 minutes. Zeiss obj. 4.0, oc. 6, x 375.

A fair picture of an experiment can hardly be given in a table or by curves. It requires a series of plates drawn from the living specimen. This has not been done, because I do not feel that my study of cell granulation and its changes during fatigue is at all complete. Hence, for the present, the following outline drawings, reproduced from camera outlines made during the experiment, may suffice. Fig. 4 represents experiment 23, <sup>1</sup> to <sup>7</sup> being successive drawings of the stimulated cell.

To begin with, we have a typical spinal ganglion cell, with nucleus situated eccentrically. The nucleus is clear, slightly oval in shape, but with perfectly even contour, as seen in optical section. After thirty minutes' stimulation, <sup>2</sup>, fig. 4, the side toward center of cell has changed, the outline here having become faint and indented. In <sup>4</sup>, the other side has begun to cave in, and so on to <sup>7</sup>, where we see a shrunken, jagged nucleus <sup>0</sup>, its original size. It has come to lie a little closer to the cell capsule, and the cell scarcely decreased in size to a measurable amount. To enter here more into detail would be to repeat a former description. The experiments are, in fact, repetition of former work under conditions varied so that we see continuously and in a single cell what we were able to find in a series of different animals and months of experimentation before. Placed in osmic acid, the nuclei retain this appearance, which fact completes the connection with former work done by the osmic acid method. It should be added, however, that the characteristic darkening of the nucleus as it shrinks does not occur in these experiments.

Considerable attention was directed toward studying changes in the granulation of protoplasm during stimulation. Some of the cells became lighter and clearer, while in others this was not so manifest. In experiment 3 the cell under observation contained several prominent oil droplets. During the first two hours one of these was observed to become smaller and smaller, and at last it disappeared. Two more, observed at first to be separate, were seen to have moved together and coalesced. Teased in glycerin, after treatment with osmic acid, the cell protoplasm is seen to be pervaded with large, irregular, light spaces, probably the vacuoles observed in sections. The entire cell is, however, too thick for such study. It was impossible also to detect indications of vacuolation in the living cell. During the whole time nucleoli were also subjected to closest scrutiny, in the hope of seeing possibly the movements described by Svierczewski,\* and of gaining some light as to the function of this organ outside of strictly reproductive processes. While in normal salt solution or Ringer's solution no movement of any sort, or only slight changes of shape and position, such as are indicated in fig. 4, could be observed, together with a gradual decrease in size. Connected with this latter it was possible to make out granules in the nucleolus, which moved slowly about, and in several instances were seen to be extruded into the nucleus. Confirmation of the above was immediately sought in sections of spinal ganglia already in my possession, and was found in abundance in osmic acid specimens stained in safranin. The granules here were stained a brighter red than the body of the nucleolus, and several were found partially extruded. In this connection I may briefly refer to experiments 31 to 33, although they belong properly to a subsequent paper. Potassium tartrate was (1 per cent) added to sodium chloride and calcium phosphate solution, with a view of giving the cells a trace of potassium and more oxygen in case there was not enough accessible in the plain liquid. The somewhat unexpected result may be seen outlined in fig. 5. The different stages represented in (small type) 1-4 were actually observed and camera outlines made in twenty-two minutes. The movement of the nucleolus in this case had every appearance of being amœboid. The nucleolus of the control cell changed shape somewhat, but retained its size, whereas the fragments of the stimulated nucleolus had all dissolved in thirty minutes. Experiments 32 and 33 gave exactly similar results, except that the control nucleoli were not observed to move.

\*Svierczewski. Zur Physiologie des Kerns und Kernkörperchens der Nervenzellen des Sympatheticus. Centralblatt f. d. Med. Wissensch., Berlin, 1869, p. 641.

A number of the briefer experiments were made with the special purpose of testing upon frogs certain results which Vas\* has recently reported from experiments upon the sympathetic ganglion cells of the rabbit. Among these results Vas describes a swelling of the cell and especially of the nucleus upon continuous stimulation for fifteen minutes, the electrodes being applied to the cervical sympathetic 3 centimeters below the superior cervical ganglion. The nuclei of these cells became swollen and clear, exactly the reverse of my results for spinal ganglion cells after a longer period of intermittent stimulation. It is of interest to note that this diametrically opposed result is obtained by stimulating the nerve in the reverse direction to that of the normal passage of the nervous impulse. Hence in these experiments stimulation was applied to the dorsal root between cord and ganglion.

Of the seven experiments under this head, 4 showed no change in the appearance of nucleus; 2, slight change, 7 to 12 per cent; 1, marked change, of about 30 per cent. All change observed was toward shrinkage, with no tendency to swell. It should be added, however, that the present method affords no adequate test of Vas's results, since (if stimulation the reverse way tends to produce swelling, and if this be anabolic in character) no anabolism would be possible in a non-nutrient solution. In the two experiments with slight change the ganglia were near the electrodes; in the one with marked effect it almost touched one electrode, so that the change produced was in all probability due to irradiation of stimulus.

In the present series no attempt has been made to do more than test under new conditions the validity of previous work. A method has been devised by which a much easier and more complete and satisfactory demonstration of fatigue changes in ganglion cells may be made. Former work has found confirmation, with the additional result that the effect produced by hours of stimulation of a nerve in the body may be obtained in a few minutes by removing the cells to a non-nutrient solution and placing them between the electrodes.

In concluding I may call attention to the fact that with the above method we have a means of studying the action of any chemical substance, medical or nutrient, upon the nerve cell itself. With modifications for temperature, it may serve equally well for mammalian tissue. It is intended to make these the next steps in the work.

---

#### DISCUSSION.

Dr. MACALLUM.—Dr. Hodge's observations are extremely interesting and instructive. It would be interesting also to determine the micro-chemical changes that occur in the nerve cells. Leheneld and Monti have shown that the cytoplasm of the nerve cell contains more phosphorus than the nucleus of the same, and if we could parallel Dr. Hodge's observation by observations with the method used by those observers we might gain a full history of the changes of the nerve cell under stimulation. Dr. Hodge's observations on the amœboid properties of the nucleolus under the influence of potassic tartrate solutions show that these bodies exhibit under certain conditions properties which are not usually attributed to them. The speaker himself observed in the gland cells of young amphibia the amœboid movement of the nucleolus, and regards this as a normal property. Bütschli found that drops of a mixture of salt, old olive oil, and albumin exhibited amœboid properties, and it is not surprising that such a body as the nucleolus, so closely connected and associated with the vital properties of the cell, should exhibit movement. It is more reasonable to believe this than to believe that because a nucleolus-like body exhibits movement as it does in certain cancer cells, that it is therefore a parasitic organism, a conclusion which some pathologists have adopted. As to the question whether pigment indicates decay or activity, Dr. Macallum thought that both views are partly true.

\* Vas, Ferd. Studien über den Bau des Chromatins in der Sympathetischen Ganglienzelle. Archiv. f. Mik. Anat. Bd. 40 S., 375, 1892.

Pigment is chemically melanin, an iron-holding derivative of chromatin, like hæmoglobin and as chromatin, as shown in the nucleolus, disappears in old age and activity, it is but natural to conclude that the abundance of melanin is an indication of past activity on the one hand and on the other of how far the cell has progressed toward decay. The nucleoli are reserve chromatin, which, in young and resting cells, is more abundant than in those of old age. This fact explains the disappearance of the nucleoli in the nerve cells of old age. With the diminution of the chromatin there must be a diminution in the number of cells holding it, and therefore Dr. Hodge's observations on the great diminution of the number of nucleoli and of the nerve cells themselves is in accordance with the speaker's observation on other cells. Dr. Hodge has done work whose value in understanding certain psychological phenomena is inestimable.

### ON THE RESPIRATORY CENTER IN THE MEDULLA OBLONGATA.

By J. GAD.

The number of muscles taking part in every normal respiration is very large; larger than would generally be supposed. It is an old and unfortunately widespread idea that the diaphragm alone is sufficient for the carrying out of a normal inspiration. It is, indeed, possible by suitable sections of the spinal cord to reduce an animal to the necessity of ventilating the lungs by means of the diaphragm alone and the degree of ventilation in such an animal will be found, at least at first, not to be below the normal. If, however, the movements of the thorax be observed, it will be seen that it now neither widens, as in the thoracic type of respiration, nor remains of unaltered diameter, as in the so-called diaphragmatic type, but that the lower and lateral regions are drawn sharply inward. And when the exposed diaphragm is watched, it is seen to descend much farther, i. e., to work much harder than before. The diaphragm requires therefore, even with the apparently purely diaphragmatic breathing of the rabbit, the continual assistance of the thoracic muscles, simultaneously stimulated with corresponding intensity, if it would not be exhausted by excessive and unsuitable exertions.

We see from this example very clearly the need for the proper coördination of a great number of respiratory muscles, whose motor roots are distributed over a great part of the spinal cord from the fourth cervical to the twelfth dorsal segment. The necessary number of functional combinations of respiratory muscles is, however, far greater, as is shown by observations which can not be entered into here. On them is based the view that a normal respiration can only take place when the intensity of stimulation of each respiratory muscle is brought into proper relation with the others. The immediate innervation areas of these muscles reach from the nucleus of the nervus facialis in the medulla oblongata down to the lumbar plexus. The simplest way of getting such a coördination is seen in the case of the muscles of the eye. The nerve cells which supply the muscle fibers of the rectus internus are found partly in the nucleus of the oculo-motorius and partly in the abducens nucleus of the opposite side, so that when the left internus acts together with the right, as in bringing the point of regard closer, a different portion of its muscle fibers are engaged than when it acts with the right abducens, as in glancing to the right. Every stimulus which reaches the right abducens nucleus finds here motor nerve cells not only of the right abducens, but also of the opposite internus, and every time the right abducens is stimulated the left internus is also stimulated in corresponding degree. In this example the coördination of two muscles is accomplished by bringing together a part of their motor nerve cells. This will not serve in the case of the respiratory muscles, neither the inspiratory nor the expiratory, for we have seen that their motor nerve cells are distributed through a long series of segments.

If we take for granted that similar ends are reached in similar ways, we may here use to some advantage our knowledge of the coördination mechanism of a certain group of movements in the frog. A very important coördinated movement in the frog is the taking of the spring position, for only from this position can he make the spring which is often his one chance for life. The spring position is assumed by bending all the joints in the hind limbs, and the motor nerves of the flexor muscles carrying out these movements have their origin in the great motor ganglion cells of the anterior horn in a series of segments of the distal portion of the spinal cord. Evidence has been brought forward that in the proximal portion, from the fourth spinal segment upward, the coördination of the muscles taking part in the assumption of the spring position is effected through small ganglion cells of the posterior horn. Anatomically expressed, the axis-cylinder processes of the small ganglion cells, together with their collaterals, stretch to the motor ganglion cells of the flexors of the hind limbs and embrace these cells with their terminal branches. Each individual ganglion cell in the first category can in this way occasion a simultaneous excitation of a number of distant motor cells, and acts as a coördinating mechanism for them. We may say that the elements coördinated by this apparatus are subordinate to it, or that the latter is a preördinating apparatus for these elements. The small ganglion cells, which coördinate the flexor muscles for the assumption of the spring position, are placed together in the proximal part of the spinal cord. They are connected in space and have a common function, and for this reason may be termed a "center," and more particularly a "coördinating center for the flexor muscles."

The combination of motor nerve cells, in the nucleus of the facial nerve or of the vagus or in the individual spinal segments, which supply the muscles taking part in respiration may be called the "respiratory muscle center," and what we have learned concerning the flexion center in the frog warrants us in assigning to some complex of nerve cells the function of bringing the bulbar and spinal respiratory muscle centers into orderly, related activity. Such a coördinating "respiratory center" would be sought, according to the usual experience concerning the location of higher coördinating functions, not in the mammalian spinal cord, but in the more proximal portions of the central nervous system. Legallois, indeed, was able to show rabbits which continued to breathe regularly after the removal of the cerebral hemispheres together with the pons as far down as the vagus roots. Death followed the removal of more distal parts, a circumstance attributed by Legallois to destruction of the vagus roots. Flourens, however, who pointed out that vagotomy was not immediately fatal, ascribed the result to the extirpation of his *nœud vital* at the point of the calamus scriptorius. It is certainly true that the destruction of a comparatively circumscribed area in this region will cause a sudden arrest of respiration and speedy death, and this spot may therefore be picturesquely called a vital knot; but that this place is not the seat of the respiratory center, as defined above, has recently been shown by me and Marinesco. Brown-Séquard in France, and later, Langendorff in Germany, have long contended that the result of Flourens's experiment is not to be explained by the non-stimulating removal of the only place of origin of the respiratory excitation, but by the strong stimulation of an inhibitory path.

To the authors just named the respiratory muscle centers are places where the respiratory excitation develops under the stimulus of the blood, but where it may be repressed by the nervous excitation transmitted by the vagus, trigeminus, and other nerves which play a reflex part in the normal regulation of the respiration. Langendorff based his opinion on highly interesting experiments of Rokitansky's on new-born animals, which Langendorff was able to confirm, namely, that such animals, if they are previously given a little strychnine, continue to breathe spontaneously some time after decapitation. It appears to me, however, that these experiments can not be made of general application with regard to the functional

independence of spinal respiratory muscle centers in fully grown animals, for it has often been shown that the spinal cord of newly born and of lower animals possesses a greater independence of the higher parts of the central nervous system than in the fully grown, in whom alone the changing conditions to which the respiration must be adjusted have reached that complexity which makes the mechanism of its regulation so interesting a problem. The logical development of the idea of the essential independence of the spinal respiratory muscle centers must lead to experiments which were made by none of the original representatives of this idea, but were first done by Wertheimer. Wertheimer took fully grown or nearly grown dogs, carried them with long-continued artificial respiration over the immediate consequences of section between cervical cord and spinal bulb and noted the behavior of the animals when artificial respiration was stopped, three-quarters to two hours later. Besides other movements, his animals showed also such as caused a circulation of air in the trachea and sufficed to prolong life three-quarters of an hour without artificial respiration. Not much weight, to be sure, is to be laid on the last circumstance, for the animals must have become cold-blooded under his method, and may have acted like hibernators, who also can live with a minimal circulation of air in the trachea. The form of the movement was the important question and concerning this four experiments of my own have given me an opinion. I used young, scarcely grown dogs and began artificial respiration directly after but not sooner than the stopping of spontaneous breathing after the separation of the spinal bulb. In order to avoid excessive cooling of the animals, I experimented on warm summer days and looked out for plenty of covering.

About an hour after the operation the animals behaved like admirable reflex preparations; when they were raised by the neck they attempted to lift the head, showing that shock had passed off; the heart beat was strong; the rectal temperature indeed had fallen. When the artificial respiration was interrupted, the animal lying upon its side, it continued at first to lie quietly, then began irregular movements in which thorax and abdomen took part, but not to a pronounced degree. From time to time the diaphragm contracted independently and alone, while between times muscles of inspiration and expiration showed a highly disordered activity. These could not possibly be termed coördinated respiratory movements, such as an animal that has not been made cold-blooded needs to make in order to preserve life. These phenomena were repeatedly observed in the same animal and showed themselves in essentially the same way in all four animals. I got the impression that the spinal respiratory muscle centers did all they were capable of doing after separation from the respiratory center; they fell into activity with the increasing accumulation of carbon dioxide, just as did the spinal nerve cell groups which call forth other movements, for example those of a limb; this activity also found rhythmical expression and could be increased reflexly like the movements of a limb; but there was no indication present that the spinal respiratory muscle centers possess a specially strong sensibility towards the stimulus of the blood. This perhaps might be due to the cooling—scarcely to be avoided in this method of experimentation—so that I can give these experiments no deciding power in any direction. The idea of the dependence of spinal respiratory muscle centers on a coördinating respiratory center in the spinal bulb was not strictly demonstrated, but, on the contrary, was not shaken; rather strengthened.

The efforts to localize the respiratory center in one narrowly circumscribed place in the spinal bulb have (as is known) led only to contradictions. Flourens, Longet, Scheff, Gierke, Mislowsky, and Hohn, have each given a different bilaterally symmetrical area whose destruction on both sides should be followed by permanent stopping of the respiration. This result is indeed to be had at each of these spots, if a coarse section is made, so that the surrounding tissue is much shaken by the instrument itself or by hæmorrhage following the section. The areas lying superficially, for example that given by Gierke, as often fail to show the result

when the section is made without shock to surrounding parts and when the hæmorrhage happens to be absent. In such experiments, however, a transient interruption may occur, but is indeed to be referred to the stimulation of an inhibitory path, for it passes off without any treatment. Too little attention is paid to the danger of being deceived by stimulation of inhibitory paths in the attempts to localize the bulbar respiratory center, although Brown-Séquard pointed out this danger long ago, a service for which we may give him credit without assenting to his conclusions.

Finally, it results from these several experiments that the attempt to confine the respiratory center to a narrowly circumscribed seat has no prospect of success. It must, indeed, excite surprise that the possibility of doing this should have been held to be so important; in fact, far more important than the demonstration of nerve cells at the place in question. We could not, indeed, expect that nerve cells which carry out a defined coördination should be irregularly strewn about in the central nervous system; on the contrary, they should be united in a well-defined anatomical system. There need, however, be no limit to the separation in space of the elements of this system, except that set by the common requirements of the cells of the center in respect of their food and their blood and lymph supply.

It was not probable that further progress in the solution of the problems we have been discussing could be made without a method by which extensive extirpations could be carried out, step by step, in such a way that each individual procedure should cause the smallest possible inhibition stimulus; that each further procedure should be made only after the effect of the stimulus of the preceding had died out, and that each successive act should permit as sure a localization of its effect as the previous one. I had seen that cauterization by laying on small pieces of blotting paper just saturated with nitrate of silver fulfilled the conditions of the above-mentioned method and I had often, before my classes, thus eaten holes in the medulla oblongata of rabbits, which included all the places given as the seat of the respiratory center, without the respiration stopping. But time was lacking for the systematic employment of the method and I was accordingly much pleased when Mr. Marinesco, who had been present at one of these demonstrations, declared his willingness to investigate the matter in my laboratory. Mr. Marinesco learned first to do the fundamental experiment, which had to be learned less on account of the requisite nicety of manipulation than to acquire a conviction of the absolute necessity of going very slowly, step by step. In these preliminary experiments Mr. Marinesco found a still better method of extirpation; burning by means of glass pearls the size of a pin's head, made by melting the end of a fine glass thread. These glass pearls are very light, and thus all pressure, all shock, and all bleeding are avoided, and the operation field is always quite clean and clearly visible. And this procedure also makes much easier the interpretation of the sections of the suitably hardened tissues in respect of the extent and the boundaries of the extirpation.

The long continued exertions of Mr. Marinesco furnished us a great number of preparations from animals who either had continued to breathe in spite of extensive extirpations in the spinal bulb, or whose often inhibited and as often recurring respiration had finally ceased after the last slight extension of the extirpation. I lay the most weight on preparations from animals in whom the extirpation was done only on one side. Such animals breathed on uninterruptedly and sufficiently with the uninjured side. They lost by far less heat than in the Wertheimer experiment, because artificial respiration is avoided and the division of the medulla, even in deep extirpations, does not take in too large a part of its cross section. When in such animals a unilateral extirpation causes the respiration to stop on the operated side and there is no return during hours of observation, in which the animal is meanwhile breathing sufficiently with the intact side, the conclusion is certain that the effect of an inhibition stimulus has passed away and that the phenomena remaining are purely the expression of a loss of function. We have had frequently the opportunity of observing such animals. The unilateral breathing may with a

little practice be recognized with a fair degree of certainty, even with unopened abdomen. We finished the observation, however, by opening the abdomen, after time enough had passed for the effect of the inhibition stimulus to have disappeared, and determining with all certainty and by direct inspection of the diaphragm that the respiration was one-sided and that the passive half of the diaphragm did not become rhythmically active even when the nostrils were closed by pressing them together. As asphyxia comes on, indeed, even this portion of the diaphragm may be drawn into the widespread irregular clonic convulsions. Observations of this sort on rabbits, cats, and dogs of different ages have fully persuaded me of the incorrectness of Brown-Séquard's, Langendorff's, and Wertheimer's views; the spinal respiratory muscle centers are not, in my opinion, relatively independent of the bulbar respiratory center but, on the contrary, are wholly dependent on the latter in their functional activity.

Although a transient disturbance of the respiration follows even a narrowly circumscribed and careful extirpation at most points on and beneath the floor of the fourth ventricle, yet a difference is to be noted. After some extirpations, as soon as the effect of the inhibition stimulus has passed off, the respiration comes back as strong as ever; but in others a noticeable weakening of the respiration remains even when it does not amount to positive failure. The areas giving the latter result lie in the *formatio reticularis*, whose nerve cells, therefore, are at least in part in relation to the bulbar respiratory center. In human anatomy, as is well known, the median part, or *formatio reticularis alba* (from the hypoglossus root to the *raphé*), is distinguished from the lateral *formatio reticularis grisea*. In man, and also in the rabbit, many more nerve cells are strewn through the lateral than through the median part of this formation, while in other animals, for example the cat, the number of nerve cells in the median part is very large. Corresponding to this, extirpations in the cat between the hypoglossus root and the *raphé*, when sufficiently deep and long, seriously impair or wholly stop the breathing, while in the rabbit the *formatio reticularis lateralis* must be removed in some extent in order to finally stop the respiration.

That the stopping of respiration after removal of the respiratory parts of the *formatio reticularis* was not due simply to the section of intra-central conducting paths leading from a more proximally situated respiratory center, but was the result of the removal of cellular elements influencing the respiratory rhythm, was shown by stimulation experiments on rabbits. In order to make a circumscribed electrical stimulation in the depths of the tissue we used very fine insect needles, which were covered to the points with a thin coat of varnish. These were united with the secondary coil of a Du Bois Reymond inductorium by means of very thin, soft, flexible conducting wires and a friction key. At the selected place the needles were passed close together through the floor of the freely exposed fourth ventricle into the bulb. The places which we desired to stimulate lay at such a depth that the needle electrodes were sufficiently fixed by the tissues through which they had been thrust, and the thinness and softness of the conducting wires permitted the needles to follow every movement of the animal, without the slightest displacement in the wound. In by far the greater number of cases the introduction of the needles and their continued presence, so long as the current did not flow through them, caused no alteration in the respiratory curve written with the respiratory volume writer (*aëroplethysmograph*). In two animals, however, very interesting attacks of coughing were observed, each attack being preceded by an interval of quiet, and it was found later that exceedingly minute hæmorrhages had taken place into the substance of the *formatio reticularis lateralis*. The electrical stimulation was made with the secondary coil as far from the primary as possible, and while the respiratory curve was being written with the *aëroplethysmograph*.

The first results which appeared with the smallest effective stimulus were seen when the needles were in the *formatio reticularis lateralis*, and only then, and con-

sisted of an inspiratory change in the breathing, namely, a quickening of the respiratory rhythm. Electrical stimulation below the point of the calamus scriptorius, and especially further distal (but still at a sufficient distance from the phrenic roots to prevent their excitation by the very weak current we were using), also affects the respiration. Here were observed, even with the weakest stimuli to which the respiration is capable of reacting, only tetanic contractions of the inspiratory muscles, on which were superposed the respiratory movements in their previous frequency and depth. Here, therefore, we have to do only with the cerebro-spinal motor conducting paths from the respiratory center to the spinal respiratory muscle centers, and this holds essentially true for the *nœud vital* also, while in the former case, where alterations in rhythm were observed, we must suppose that nerve cells were in action, and these nerve cells must belong to the respiratory center itself. The descending motor conducting paths were localized by Schiff in the lateral columns of the spinal cord. Mr. Marinesco was able to confirm this statement by the use of his method of progressive cauterization. He made this extirpation on one side between the first and third spinal root, and we considered the path in question wholly interrupted when the respiration on the same side did not return after an hour's interval nor in dyspnœa (the diaphragm being exposed for inspection and the animal continuing to breathe with the uninjured side). Mr. Marinesco was able to give the situation of this lateral path more exactly: In the *processus reticularis*, or lateral column at the base of the anterior horn. This is very satisfactory, for the reason that the bulbar continuation of the lateral column is to be sought in the *formatio reticularis*, whose cells are concerned in the function of the respiratory center. I hold this result to be indeed specially satisfactory, because the demand that a center subserving a definite function shall be a demonstrable group of nerve cells, for example, a group like the nucleus of a motor cerebral nerve, appears to me to rest on a preconception wholly without foundation. A coördinating mechanism of the highest order for such an extensive motor apparatus as that for respiration requires too large a number of nerve cells to make the realization of such an idea possible. All that can be demanded is that the nerve cells which subserve the function of the respiratory center shall be so arranged that they may be brought into relation with the respiration without conflicting with the histologically grounded conception of the systematic structure of the central nervous system. It is exactly here that the coincidence between the localization of the spinal path and the bulbar cells becomes so satisfactory.

There are physiologists who refuse all conceptions of a respiratory coördinating mechanism founded on an anatomical basis. A representative of this school (Langgendorff) has recently expressed his views on this question as follows:

“By respiratory center should be understood the sum of the individual centers of the respiratory nerves, which must be conceived as united in a physiological union.”

The fact of the common harmonious working of nerve centers widely separated from each other and supplied with blood under different conditions can not, however, be explained by the existence of a fixed chain of ideas in the head of a physiologist. In order to reach a scientific explanation, from which we are, indeed, still very far off, we must make an earnest attempt to get a definite idea of an anatomical connection between these centers which can serve as a basis for exact physico-chemical conceptions. Only such hypotheses can point the way to fruitful experimentation, and only such (not metaphysical dicta) can be matter for scientific discussion. An hypothesis permitting such discussion has been recently advanced by Exner and Grossmann. They also believe that they can do without a coördinating center which shall preöordinate the respiratory muscle centers. Grossmann attempted to separate the bulbar respiratory muscle centers (facial nucleus for the respiratory movements of the nose and vagus nucleus for those of the glottis) from each other and from the spinal respiratory muscle centers by successive sections. He believed

he could establish the law that so long as any two of these centers were in connection they continued to functionate, but that each ceased to functionate as soon as it was completely isolated from the other.

Grossmann found that a section between the facial nucleus and the vagus nucleus stopped the respiratory movements of the nose, while those of the glottis and thorax still continued. He found further that a section between the vagus nucleus and the spinal cord stopped the thoracic movements, while those of the nose and the glottis continued; and, finally, he observed, on the other hand, that the movements of all three, nose, glottis, and thorax, ceased after two sections were made, the one between the facial and the vagus nucleus, the other between the vagus nucleus and the spinal cord. These experiments led Exner and Grossmann to the conclusion that the motor nerve cells of the various respiratory muscle centers must be united with each other by nerve conducting paths in such a way that each of these nerve cells communicates its excitation not only centrifugally to the muscle fibers dependent on it, but also within the center (intracentral) to the nerve cells of other respiratory muscle centers. Against this hypothesis is to be urged that the only test which the authors' experiments have undergone from other hands has failed to confirm in the most important particulars the observations on which the hypothesis is based. Frederic and Bienfait declare that they have seen the respiratory movements of the glottis continue after complete isolation of the vagus nucleus by section between vagus nucleus and facial nucleus, as well as between the vagus nucleus and the spinal cord, while the movements of the nose and the thorax stopped. This announcement is the more worthy of attention for the reason that after the above-mentioned sections have been made only the vagus nucleus remains in connection with the respiratory center demonstrated by Marinescu and me, in the *formatio reticularis*. But a serious mistrust of the Exner-Grossmann hypothesis can be justified even without a repetition of their experiments, for their hypothesis is grounded on the assumption that the motor ganglion cells can send an impulse in two directions.

Each motor cell possesses, as a rule, only one axis-cylinder process, and we know with certainty that the excitation is sent out of the cell by the way of this process. Impulses reach the cell, in all probability, by means of protoplasmic processes, and we know no histological difference between the protoplasmic processes that justifies us in selecting some for afferent and others for efferent impulses. That the cell would receive and send out impulses by the same path appears improbable when the classical experiment of the centripetal stimulation of the severed anterior spinal roots of the frog is called to mind. The fully demonstrated power of nerves to transmit impulses in two directions requires that the impulse arising from this stimulation should reach the motor nerve cells. As, however, it is known that the stimulation has no visible effect, the impulse can not have been transmitted over intracentral conducting paths. It is most probable that it does not pass the motor ganglion cells or, perhaps, does not even enter them. These reflections, indeed, rest on too uncertain a basis to themselves overthrow the hypothesis in question, but they at least point to experiments by which it may be tested. The hypothesis was born of section experiments and must withstand the test of stimulation experiments. If the Exner-Grossmann hypothesis is correct the isolated stimulation of a single respiratory muscle center should strengthen the respiratory movements depending on the remaining respiratory centers. If our conception of a preordinating respiratory center in the *formatio reticularis* is correct a narrowly circumscribed stimulus can influence in the same way, respiratory muscle centers lying far apart from each other only when the stimulus reaches the *formatio reticularis*.

Mr. Arnheim undertook the experiments in my laboratory in Berlin. We first devised a method for writing the respiratory movements of the nose on the kymographion simultaneously with the respiratory volume curve. When the stimulation experiment described above was repeated with this method, it was seen that when

the points of the two needle electrodes were passed into the *formatio reticularis lateralis* the quickening in the frequency, which we already know to be a certain indication of a minimal, i. e., barely effective, stimulation, was not limited to the respiratory movements of the thorax, but those of the nose were influenced in the same way. This result would not oppose the hypothesis under examination, provided it is accepted that our stimulation current reached the *vagus nucleus*. We ourselves believe that this possibility can be excluded with certainty, but it is difficult to furnish evidence that will convince others of this.

The above-mentioned result of the minimal stimulation of the *processus reticularis* in the proximal part of the cervical cord, consists in an increased tonus of all the thoracic muscles of respiration without any alteration in the frequency and depth of the individual respirations, a fact that was interpreted by us to mean that we had to do here not with a center, but with an intracentral motor path. This path might lead from the *facial nucleus* through the *vagus nucleus* to the spinal respiratory muscle centers (Exner-Grossmann), or might connect over respiratory center with the spinal respiratory muscle centers. According to the Exner-Grossmann hypothesis we must expect that the stimulation of the path would influence the nasal and the thoracic breathing in the same manner. The experiment, however, shows very decidedly that this is not the case.

As the stimulus increases to the point at which the increased tonus of the thoracic muscles of inspiration is produced, and alteration indeed appears also in the nasal movements, but is of quite another character and differs especially from the reaction of the thoracic inspiratory muscles in that it outlasts the stimulation. This and other of its remaining peculiarities characterize it as a reaction to a painful stimulation, which reaction appears always much earlier in the nose than in the thorax. We have never seen an increase of the tonus of the inspiratory muscles of the nose caused by stimulation of the spinal respiratory path, and we believe, therefore, that this path connects our respiratory center in the *formatio reticularis* with the spinal respiratory muscle centers, and that its excitation produces a visible effect only at one end of the path. An analogous path must exist, according to our conception, between the respiratory center in the *formatio reticularis* and the *facial nucleus*. The result of the stimulation of this path must be limited to the nasal movements. In fact, we have succeeded, with the aid of the needle electrodes, in finding places at the distal end of the *facial nucleus* whose stimulation to the effective point causes only increased tonus of the nasal muscles, in which the thoracic muscles do not participate.

The existence and meaning of this path may fortunately be still more clearly shown by a combination of the stimulation and the section experiment. It is well known that Martin, Booker, and Christiani have found places in the neighborhood of the *Aqueductus Sylvii*, at which different and well characterized reactions in the breathing can be produced. However slight are the reasons for calling these places "centers," after the example of their discoverers (they are probably only points in an important conducting path), the phenomena described by the authors named can always be reproduced with certainty. Christiani's "Inspiration center" has especially helped us to instructive reactions in the study of the more distal respiratory centers and paths. These reactions have a very clearly marked character, the same both in nasal and thoracic breathing. If an unilateral section is made between the *facial nucleus* and the *vagus nucleus* and the Christiani "center," stimulated on the opposite side, the nasal and thoracic reactions do not appear, while on stimulation of the injured side they appear as before. It follows from this experiment that we have to do here with crossed paths, and that the influence which the "center" exercises on the *facial nucleus* is not transmitted to it by the shortest path. If this were the case only those sections which are proximal from the *facial nucleus* would prevent the reaction. As distal sections also do this, the impulse can not pass by the shortest way, and an explanation of the circuitous

path is required. An explanation indeed can at once be given on the basis of our conception that all impulses, which affect all the different parts of the respiratory motor apparatus in common, reach them only by the agency of a coördinating respiratory center, which is preördinating to all respiratory muscle centers. The experiments recently made by me in association with Mr. Arnheim, as well as those first described (Gad and Marinesco), show that the seat of this center is the formatio reticularis lateralis. Our efforts to define the upper boundary of this center were at first not wholly successful, but we are now able to state that the center does not reach up to the facial nucleus, basing our statement on the previously mentioned result of the stimulation immediately distal from the facial nucleus. We see that this stimulation influences only the nasal breathing, and does not, as does the stimulation of the respiratory center, affect the nasal and thoracic breathing at the same time and in the same way. We have made good progress towards giving the preördinating respiratory center a definite place among objective things.

---

#### DISCUSSION.

Dr. Reichert said that the paper was one of considerable interest to him because his work is a practical demonstration of what Dr. Reichert has taught for years to the students in the medical department of the University of Pennsylvania, i. e., that the various motor nerve centers which are concerned in the complex coördination movements of respiration are undoubtedly governed by a pre-coördinating center.

Dr. Beyer, discussing Professor Gad's paper, said that the highest credit was due to the Professor for his work on the innervation of respiration; the formatio reticularis was always considered among nerve anatomists and physiologists as a very dark knot. Its connection, therefore, as a preördinating center of respiration is to be welcomed very heartily.

#### AUTOMATISM IN NERVE CENTERS.

By SAMUEL WOLFE, A. M., M. D.,

*Clinical Professor of Nervous Diseases in the Medico-Chirurgical College, Philadelphia (formerly Professor of Physiology).*

The so-called stage of rest in any physiological unit should be considered when regarding its total functional activity. This stage in the nerve cell must be continually influenced by impressions on the peripheral nerve endings sending impulses over fibers, which impressions arise in the external world, within the body from similar causes, and as the result of metabolic processes in the various tissues. The intimate connection by fibers of all the nerve cells makes it probable that no function of the cell is independent of impressions arising outside of the immediate cell concerned, hence not automatic in any absolute sense. A stability which prevents activity independent of excitation transmitted through a fiber is essential to the normal condition of most of these cells, and most probably of all of them.

#### INNERVATION OF THE VENA PORTA.

By FRANKLIN P. MALL, M. D., of Chicago, Ill.

It has been known for a long time that when the splanchnic nerve or cervical spinal cord is irritated the arterial pressure rises. During the irritation of these nerves it has also been noticed that the smaller arteries of the mesentery as well as others contract. The mechanical explanation of the rise of the arterial pressure was therefore quite simple. When the volume of the blood in the arteries, as well

as that thrown from the ventricle, is taken into consideration, it is at once seen that the simple contraction of some of the smaller arteries is not sufficient to explain the rise of arterial pressure after splanchnic irritation. It has been found that when the aorta is tied just below the left subclavian artery (and the femoral artery opened to prove that the arterial pressure is reduced to zero), irritation of the splanchnic nerve causes a decided rise of pressure in the carotid artery. Moreover, it is found that with the aorta open or closed splanchnic irritation causes an increase flow of blood to and from the heart, thus showing us that the real cause of arterial pressure is due to an increased amount of blood being thrown into the aorta. A similar rise of pressure can be produced by injecting a quantity of fresh blood either into the jugular vein or into the carotid artery. In a dog of average size splanchnic irritation causes an increase of about 100 c. c. of blood to be thrown into the aorta. Transfusion of the same quantity from another animal causes an identical arterial curve.

The first and most important experiment is the proof that when the splanchnic or the cord is irritated the vena porta contracts, often completely emptying its lumen. That this is not primarily due to a contraction of the smaller mesenteric arteries is proved by the fact that the contraction of the vein is most marked when the pressure in the abdominal aorta is reduced to zero. Moreover, with the aorta open and the vena porta closed, it is quite easy to cause the portal pressure to exceed that of the arterial by splanchnic irritations. We therefore conclude that the rise of arterial pressure, after splanchnic irritation, is due in great part to an increased quantity of blood being thrown from the heart; this, in turn, is caused by the contraction of the veins, and especially the vena porta and its branches. (*See Archiv. für Anat., und Physiol., Paynol, Abt., 1892.*)

In the demonstration to be made a ligaturestaff is applied to the aorta just below the origin of the left subclavian, and on the splanchnic is armed with an electrode. The portal vein is exposed, and after the artery is closed the splanchnic is irritated. The portal vein will contract and the arterial blood pressure will rise.

---

## HIBERNATION AND ALLIED STATES IN ANIMALS.

By WESLEY MILLS, M. A., M. D.,

*Professor of Physiology in McGill University, Montreal, Canada.*

In a paper read on this subject before the Royal Society of Canada in 1892 I made reference to the views entertained in regard to the winter sleep of a number of animals, which will, however, be omitted from this paper in order to shorten it. My own studies were conducted chiefly on our American marmot or woodchuck (*Arctomys monax*), and of these I now give some account, together with details of some cases in man of hibernation or an allied state, one of these being, I think, about the most remarkable on record.

The object of my investigations being to ascertain not only the nature of the winter sleep, but the character of its variations under a changing environment, especially as regards temperature and meteorological conditions generally, I kept the animal in different rooms of the houses in which I dwelt successively through the creature's lifetime, and also in different parts of an outhouse in which my dogs, fowls, etc., lived. It would take up too much space and prove rather wearisome to attempt to reproduce here the records which I have kept in detail. It will be both more practicable and more profitable to give the general results of studies on this one specimen for the four years during which he lived, and then refer to the unexpected result of the study of another specimen during the past winter.

I think the following life periods were recognizable in the specimen I had under observation: (1) A period characterized by either drowsiness or sleep or profound torpor, lasting from about November to April; (2) a period of perfect wakefulness immediately following, during which the animal was emaciated, in poor coat, and with a general low vital capital, lasting for some weeks; (3) a period of improving condition, with good health and a desire to get free, which latter was also noticeable in the preceding period; (4) a period of maximum weight and vigor, with perfect coat and an abundance of fatty tissue. But little need be said about any of these life periods except the first. During the second the emaciation increased rapidly at first on waking, and was equally marked by voracious feeding. The meaning of this will be referred to later. It is plain that the organism entered on its long period of diminished vitality with a large stock of reserve material, and it is equally clear that this was drawn upon to the full.

I now turn to the peculiarities of the sleeping or torpid condition. I have characterized the first period as one of drowsiness, or sleep, or torpor, because there are subdivisions of the first period, during which the animal was found in a condition that was characterized by drowsiness, and no more; again, it was plainly only sleeping, while again it was as profoundly torpid as it ever became. The period of most profound sleep was never reached all of a sudden, but was preceded by the two states referred to above. Moreover, as the depth of winter approached the sleep became more profound, and the reverse with the approach of spring, so that we might represent the depth of the sleep by a rising followed by a falling curve with a rather long flattened top. During the whole of the first period the animal nestled in the straw, with which he was always provided, and when he was most profoundly unconscious but little of him could be seen often, so completely was he covered. Another important matter. The amount of food consumed was directly proportional to the depth of his sleep. Not only did he eat less frequently, as a matter of course, but the quantity taken at one time was less. Occasionally when fully hibernating he would awake to fall asleep again, merely after gathering the straw about him a little closer, and not eat at all. His cage always being supplied with food, there was no doubt about his ability to provide himself when so inclined. His excretions were also in proportion to the amount of food consumed, and especially to the depth of the sleep. The less he ate, and particularly the more profoundly he slept, the less were his evacuations when he awoke. He never befouled his bed, but always left it to void urine and feces. During the period of mere drowsiness the animal would be awakened by a gentle rustling against its cage, and even when asleep a noise would always arouse it; but when in a torpid condition it could not be thus aroused, but might be handled without being brought to the natural condition, though handling and much less disturbance always caused movement—a phenomenon to be discussed later.

In the spring of 1891 my woodchuck came out of his winter sleep in a very emaciated condition, and this, as usual, increasing after his awakening, he was in a doubtful state; but the case was soon decided against the animal in consequence of my servant having left him for some time fully exposed to the sun's rays. An autopsy revealed the fact that the animal (a male) was the subject of tuberculosis of the lungs, though possibly but for this exposure he might have lasted another year.

Through the kindness of Mr. R. F. Rorke, an undergraduate in medicine of McGill University, I became possessed of two specimens of the marmot in the latter part of the summer of 1891. One of these was very large and in fine condition, and his escape soon after arrival has been a frequent subject of regret by me, as I hoped to be able, not only to continue the observations, but to make them comparative, as it was my intention to keep both under the same conditions, in fact, in the same cage. But the curious part remains to be told. Though I kept the remaining woodchuck under exactly the same conditions as the animal I had so long had, he did not hibernate for an hour during two winters, though he drowsed and slept enough.

It has been generally considered that the hibernating condition of animals was dependent above all else on the temperature of the surrounding atmosphere. My experiments on bats seemed to warrant this conclusion, for whenever the temperature reached the neighborhood of 45° F. to 40° F., the other conditions being favorable, my specimens began to hibernate. It was also true that my woodchuck was in the deepest sleep during midwinter, when the cold is greatest. Whether a bat could be put into a state of torpor during summer by exposing it to a lowered temperature I do not know. However, Marshall Hall maintained that the diurnal sleep of the bat ("diurnation") was exactly the same phenomenon as the winter sleep. The same writer maintained that hibernating bats always awoke when the temperature fell below freezing point, and his observations showed that the temperature of the animals was always a few degrees above that of the surrounding atmosphere. Probably Hall is correct in the main, for my bats when the temperature sank during the night much below freezing were always found dead in the morning. Whether they awoke first or simply passed from torpor to death I do not know. However, for the marmot I can assert positively that this rule does not hold, for frequently the water was found frozen in the apartment in which the animal was kept, yet he was undisturbed. Nevertheless, I came to the conclusion that this exposure is injurious to a hibernating animal, and that it had something to do with the poor condition in which my specimen was found in the spring of the year in which he died.

Before discussing the true nature of the phenomena of the winter sleep, I call attention to certain cases of allied nature. Such frequent references as we find to the hibernation of swallows deserve some consideration. It is also stated that in Scotland sheep have been found alive after being buried for weeks beneath the snow; and Dr. Frank Miller, of Burlington, Vt., reported when a student, to the Society for the Study of Comparative Psychology, at Montreal, that hogs had been found alive after being accidentally imprisoned below the surface for several weeks; longer than it seemed possible for them to survive under ordinary circumstances, so that it would appear they had been in a condition of hibernation, or some such state.

Turning to the human subject: We have all read of instances in man of "suspended animation" or "trance." The case of fakirs in India having been buried alive, exhumed and resuscitated after months is attested by such evidence as it is difficult to set aside, however hard to credit. Mr. D. W. Ross, a student in medicine of McGill University, has gathered the facts of a peculiar case in so far as they are now obtainable. The individual in question was known as "Sleepy Joe," a farmer by occupation. He was married and had several children, one of whom, a girl, had the same drowsy appearance as her father. This man would sleep almost constantly for several weeks, awakening, however, to attend to nature's calls and to take food. He would at times awake more fully and then set to work, whether it was day or night, and almost incessantly labor as if to make up for lost time. He was rather weak mentally, but appeared ashamed of his sleepy tendencies, which seemed to get worse as he grew older. He lived to be about 60 years of age.

Dr. Aug. Robinson, of Annapolis, has kindly given the following notes of a unique case:

John T., son of a pensioner, is now about 62 years old. When he was 28 years of age his father committed suicide by cutting his throat in a fit of insanity. Before his father's death John had shown symptoms of melancholia. He would sit by the hour over his father's cobbler's bench laughing and talking to himself and working himself into a frenzy, fighting imaginary foes, and going into immoderate fits of laughter. I can not ascertain, after much inquiry, how long this condition of things lasted before he lapsed into his present state; but this much is certain, for the last thirty years or more, about the end of September every year he falls into a deep sleep or stupor, and, as his present condition is a fair sample of the manner in which his winters have been passed since he was first attacked, I will describe him as I found him on Monday, December 10, 1888, and repeat what I was told by his friends regarding his attack this autumn:

About August 31 Jack went to bed after eating his evening meal as usual, without exhibiting anything out of the common in his manner or otherwise, or giving any

SUBJECT IN HEALTH.

SUBJECT IN A STATE OF LETHARGY.

reason for the supposition that he was out of sorts in any way. On the following morning he did not get up, nor has he shown any more vitality than any sleeping man up to this time. His sleep is very quiet, without any stertor; indeed, it is as calm as that of a child. Twice in every twenty-four hours he is taken up, a person supporting him on each side, holding a vessel for his convenience. He knows enough to voluntarily empty his bladder. The urine is high in color and scant in quantity. About 11 o'clock every night he seems to show rather more life than at any other time, and advantage is taken of this to pour a little thin oatmeal gruel, beef tea, or soup down his throat, he opening his lips to allow them to do so, and slowly swallowing it. He only takes a very little each time, and if urged to take more simply keeps his mouth shut. About once in every thirty days, not exactly at regular intervals, during the evening generally, the family will hear a peculiar chattering noise. They never take any notice of it, for they know it is Jack going down to the outhouse to empty his bowels. He then returns to his bed and sleeps. He knows enough to throw a quilt over his shoulders at such times.

At the time of my visit I found his temperature 96° F.; pulse 60, regular, though not strong; respirations 14, easy and quiet; skin cool. A pin stuck into his arm caused no apparent change, and he might be pinched until black and blue without its causing him the slightest uneasiness.

My first visit to Jack was about twenty years ago, when I first came to live and practice in this vicinity, and it came about in this way. Of course there was a talk about the new doctor and what he could do, so I was called to see this queer case. I got all the particulars from the friends and neighbors, and what means had been tried by other doctors, and then I promised to try what I could do. On the following day I went again, accompanied by my brother, also a physician. We took with us a good galvanic battery. One of the handles was placed in each hand and bound closely to the fingers with wet bandages. We then put on the full power of the instrument. Poor old Jack was out of bed in an instant, and I shall never forget his look of astonishment and horror as he yelled out, "Damnation, what's that?" I can also well remember my own feelings of satisfaction and complacency when the natives congratulated me on my success in this, my first case. I walked off as if saying to myself, "I knew I could do it." Well, Jack remained awake about three days and then I got a message that my patient was off again. I went up and tried the battery a second time, with only the effect, however, of making him open his eyes and grunt out "Eh," in a querulous manner, and after looking about him for a half hour or so, he lapsed into his former condition. Next day I again tried the battery, but without the slightest effect, so I gave it up as a hard case.

This is all I have to say about this singular object, except that, of course, he becomes very thin and haggard before he rouses finally in the spring, and he does not fairly waken until the end of May or first of June. During the summer months Jack does exactly the work he is told to do, but he must be told over again every day; for example, if desired to bring the cows from pasture, he will do so, but will not milk them until told to, nor will he turn them afield again without being desired. He does not seem to know what to do next, even though the same routine is carried out every day. An exception, however, must be made in one respect. He does not require to be told when dinner or tea time arrives, and is blessed with an excellent appetite. Jack is always ready for his food, and is not particular about quality, so that quantity is there. He will talk quite rationally on any subject when spoken to, and recollects distinctly most of the incidents of his childhood. He will hold animated confab with the cows, dogs, trees, wheelbarrow, or any other object which happens to be in his way, and may be noticed sometimes lecturing a tree for some time, breaking out occasionally into uproarious fits of laughter.

When visiting in 1890, Dr. C. K. Clarke, superintendent of the Asylum for Insane in Kingston, he happened to make reference to a peculiar individual known to a few as "the sleeping woman." It at once occurred to me that her case would prove a study of great value if it could be carried out, and I suggested to Dr. Clarke that he endeavor to supplement such facts as we could learn and such observations as we were able to make by a joint visit to the subject of this peculiar condition by a careful study of the case. He succeeded much beyond my expectations in doing this, and has published the results of his investigations in the American Journal of Insanity for October, 1891, under the title, "A case of lethargy," and from that paper I extract the principal facts in regard to this case, which is so remarkable that it may be well to state them somewhat fully.

Several seasons ago I heard that there was a patient who had been in a trance for years, and from time to time word was brought to the effect that the condition still persisted, and that all efforts to rouse the woman were without result. A little more

than a year ago I obtained permission to visit the patient, but was not allowed to make any extended examination. On entering the room I found a thin, old woman in bed, apparently fast asleep. Her respirations were irregular, and varied much during the visit (lasting almost half an hour), running all the way from 24 to 44 per minute. The pulse quickened in a marked way during my stay, and ran up from about 80 to 120. The woman had her eyes half closed, and to all appearances was oblivious to everything that was going on. The nurse gave many details regarding the patient, and made a number of statements, some of which I shall repeat in a few minutes. Many of these statements we were able to verify at a subsequent period; others were undoubtedly inaccurate. Before going into details regarding the everyday life of this case of lethargy, as we saw it, perhaps it would be well to give a brief outline of the history of the patient. Unfortunately, it has not been found possible to get as many important facts as could be desired in connection with this history, but great care has been taken to eliminate all doubtful points. The patient was born in 1820 or 1821, and when she came under observation was almost 69 years of age. The neurotic history was pronounced on "both sides of the house," evidence going to show that her father had suffered from melancholia. A reliable person states that the father died from "softening of the brain"—possibly general paresis. The patient's mother was subject (a member of the family states) to attacks of partial loss of reason, which could only be cured by change of air and surroundings. It has not been possible to get an accurate account of these attacks of "partial loss of reason." The patient's early history is not well known, but it has been stated on good authority that she was "peculiar," and in childhood complained of some head trouble that caused her to keep her hair cropped short. She was married when very young, probably when 17 or 18 years of age, as she was but 21 when her third child was born. Three years after the birth of her last child she was noticed to undergo a change in disposition and acted "strangely." She could not be depended on, was untruthful and whimsical, and worried a great deal about trifles.

It is from a subsequent period (three years later) that the history of this case must be dated. The son, the youngest child, says:

"The first recollection that I have of mother's sickness was when I was 6 years old. My little sister had died, and I was just recovering from an attack of scarlet fever when she was taken down. I think the attack was caused by grief over sister's death, and overexertion and want of rest. I do not remember how long she was sick at that time, but I recollect that her left side was completely paralyzed, and that after a time a strong liniment was used, which partially removed the paralysis, and when she went to the country for several weeks she came back well. The second time that she was taken sick was when I was 12 years old. She felt poorly for some time, and was then taken with fits, or convulsions, which lasted for, I think, three days, having sometimes four or five in an hour. She was confined to her bed for, I think, about two years, in very much the same condition as at present. I do not know what curative means were employed, but she gradually improved a little, and was again sent out into the country, where she seemed to recover. She enjoyed pretty good health for about six years, but had to be very careful; she never drank tea or coffee, and always had to have the hair on the back of her head cut short. About this time her father was taken sick and we moved into his house to take care of him. This seemed to affect mother and after a short time she was again taken with fits and soon went into her former condition. During this sickness, which lasted about two years, she used to sit up a great part of the time and appeared to be perfectly conscious. She knew father and those who waited on her; used to call me her boy, but appeared to be in a sort of a stupor most of the time. She was again sent into the country, and came back well. Then ensued a brief interval of about two years, during which time she was in fair health, but was again taken down as before, and was sick for nearly seven years. During part of this time she was very low and we watched day after day at her bedside expecting each day would be the last; but she again rallied and gradually her bodily strength and reason returned to her. She was well for about five years, when she seemed to be taken with a low fever and gradually went down to her present condition."

Such is the son's account of the case, and from it we learn that the history of nervous trouble dates back at least forty years, and the inference is that the first indications of lethargy then made their appearance. The details of the conditions that existed during the different attacks are almost entirely wanting and it is unfortunate that we are left almost completely in the dark regarding the nature of the convulsive seizures that occurred. Subsequent history would lead us to believe that these were in all probability hystero-epileptic in origin. About the year 1862 the patient fell into a state of lethargy that lasted for seven years or more. The condition was not one of complete unconsciousness and, although the woman appeared to sleep almost continually, occasionally she would wake up for a minute or so at a time and converse in a rational manner. It is not possible to make more than general statements in regard to these attacks, but it is beyond doubt that the

conditions were not identical with those that characterized the last attack. Evidently the condition of lethargy was not so profound. The announcement of the death of a warm friend was the immediate cause of her awakening. The return to even an approach to a normal condition of health was a very gradual process. She was lachrymose and childish for some time, and could not use her limbs properly for months; in fact, had to learn to walk again.

During the period of wakefulness that now ensued—seven years or more—the patient, to a certain extent, interested herself in the affairs of every-day life. She went about the house; but was very quiet and did not seem able to concentrate her mind on anything. Her memory was markedly deficient, and she seemed astonished to find people and places changed, and could not realize the fact that she had been asleep for such a long time. When waking up from her long sleep one of the first requests made was for beer, and, strange to say, the same want was expressed many years after when arousing from a subsequent attack.

About thirteen years ago the patient gradually passed into the condition in which we saw her. At first she spoke occasionally, but in a childish manner, and often made a request for meat and potatoes, invariably using the following words: "Meat and potatoes; a plate all full up to the top."

Before giving the details of the case as we saw it, it will be well to repeat, in a general way, the statements made by the nurses who had the care of the patient before she came to the asylum: She seems to exercise a certain amount of discrimination regarding her food and will eat enormously or not at all and when her appetite is not lost does not seem to know when she has had enough. Her diet is made up of minced meat, potatoes, soft toast, milk, etc., and she is particularly fond of meat and potatoes—in fact will not touch anything until meat and potatoes are provided. She does not like sweet things. When not suffering from diarrhea she eats three times a day. She eats as much as any healthy, active woman of her age. She objects to nauseous drugs and endeavors to push the spoon away with her left hand. The attitude during the day is quite different from that assumed at night, and the patient undoubtedly sleeps more soundly at night than during the day. In the daytime her legs are extended; at night drawn up. In the daytime she is put either on her back or right side, at night on her left side, and remains in this position until morning without moving; in fact she can not roll over. She will not settle down for the night until a drink of cold water is given. In the daytime, sometimes for an hour or so at a time, she appears to be nearer a condition of consciousness than at any other time. This occurs generally after breakfast, but she has to be roused for her meals. When heavy coverlets are put on the bed, she attempts to shove the blankets off with her left hand, apparently preferring to be very lightly covered. The eyes are three parts closed during the day and completely closed at night. The face sometimes becomes flushed. She never speaks and, in fact, has spoken but once in eleven years or more and that was quite recently (1890), when she said, "I am not asleep." Her appetite has been better since she has been in the long sleep than it was before and she eats things she would not touch when awake. At least once during the present attack she has, unassisted, got out of bed and there is reason to believe she has done the same thing several times, but not within three years, as her physical condition renders it impossible. Several times the nurse fancied the patient was moving about the room at night, but for some time could not actually prove that such was the case. At last, however, a fall was heard in the middle of the night, and the patient was found lying fast asleep at the bottom of the stairs, down which she had fallen. During the present attack she has fasted on several occasions, and once went fifteen days without food. It must be remembered that the nurses were speaking of the last attack and at a time when the patient had been in a state of lethargy for more than eleven years.

In September, 1890, I saw the patient with Dr. Clarke. This was my first, but Dr. Clarke's second visit. We found the patient, an old woman, in bed. She was lying on her back with her eyes half closed. Her face when we first entered was somewhat flushed and respiration rapid. When respirations were closely observed it was noticed that they were most irregular and at times ceased for several moments. They averaged 22 per minute. Pulse was 104, fairly strong and regular; arteries almost free from rigidity. Axillary temperature, 98.6°. The nurse stated that ordinarily the patient's bowels moved but once in three days, but latterly she had developed a tendency to diarrhea and since that had evinced a sense of discomfort until the bowels were relieved. This sense of discomfort was evinced by whining like a dog. Ordinarily she would not give any indication that she wished to relieve herself, but the presence of the bedpan would excite the reflexes. She does not soil the bed. The statement of the nurse in regard to the amount of urine passed every day was that a little more than half a pint would be a fair average. A physical examination of the patient was made. The left foot was drawn as if there were a contracted tendo-Achillis; right foot drawn down, but not in such a marked manner as the left. Marked rigidity of the right knee and leg; left leg and knee not rigid.

Right ankle easily moved; left rigid. Patellar reflexes absent. Tickling the soles of the feet did not cause any evidence of sensibility. Each great toe was drawn under the second toe, this condition being especially marked in the left foot. When the soles of the feet were tickled it was thought that the respirations were slightly deepened, but on account of the irregularity of the breathing it was difficult to determine this point and it was considered undecided. Patient's hair gray; nails healthy and not abnormally brittle. Facial reflexes better than reflexes in any other part of the body. Orbicular reflexes good even with air; at the same time it was noticed that flies crawling over the face did not excite the reflexes. Pupils responsive to light. Small bedsores found on hips and evidence of former deep-seated bedsores plainly visible. While we were present the nurse endeavored to arouse the patient and tried to get her to take some food. A protest was made (whining), the patient winked for a few moments, and then went off to sleep again. Bread was put in her mouth, but remained there without any effort being made to swallow.

On October 9, 1890, the patient came under Dr. Clarke's care, and a series of observations of the most complete character was made. The patient, a thin old woman, apparently not weighing more than 60 pounds, was carried into the infirmary from the ambulance, and placed in bed. She was asleep and did not seem disturbed by the jolting to which she had been subjected. Her temperature was  $97.2^{\circ}$ , pulse 107, and respirations 20. Efforts were made to arouse her, but without avail. Friends stated that she had been in her present state of lethargy for more than eleven years. Her eyes were half closed, and it was found almost impossible to get her to swallow anything. Next morning her temperature was about normal; pulse 117, respiration 18; still asleep with the eyes half closed, as she remained nearly the whole time she lived.

She was under observation from October, 1890, until February, 1891, when she died. In these four months she was closely watched and until the last week of her life gave little indication that she had the slightest knowledge of the fact that she lived. She would remain in any position in which she was placed in bed, and if not fed would undoubtedly have died without making any sign that she required or desired food. Her temperature was almost invariably subnormal, sometimes falling to  $95^{\circ}$ , although occasionally it would rise to nearly  $102^{\circ}$ , without any cause that could be determined. Her appetite was capricious, although she undoubtedly had decided likes and dislikes in regard to food. She preferred beef and potatoes to anything else. The process of eating was very slow, and sometimes it would be more than an hour before she could finish a meal. When she drank anything milk was evidently preferred. She was very clean in her personal habits, and never soiled the bed. The quantity of urine passed was very small, not averaging more than one-seventh of normal. The bowels moved but seldom, sometimes only once in six or seven days. It was possible to rouse her for a moment or so, to the extent of making her open her eyes, but beyond this she would give no indication of consciousness, and went to sleep again immediately. Her legs were nearly always drawn up, although when the patient was admitted it was stated that she always straightened her legs at night. Her feet were almost invariably very cold and the hands sometimes so. Occasionally her eyelids would tremble and quiver, just as they will in a patient suffering from hysteria. Generally when much bothered she would for a few moments make a sort of whining protest. The facial expression was quiet, almost deathlike, under ordinary circumstances, but sometimes when undergoing examination an expression suggestive of pain would appear; at the same time it is questionable if pain was really experienced, as the heart and respirations did not show the least disturbance. A large amount of food for one so frail was consumed in a day, although on some occasions the appetite was completely lost. Sometimes when suddenly disturbed she would start nervously, and her hands would tremble. Trained Nurse Osborne, who was with her very constantly, seemed to think that there were times when she was nearer a condition of consciousness than at others and as this statement was also made by the former nurses, possibly it is correct. Occasionally she would push down the bedclothes with her hands and the history of the case would go to show that heavy coverings were always objectionable. Nearly every day she was propped up in a chair for half an hour. This did not seem to have any effect on her general condition.

The account of her last days are interesting. Early in February, 1891, a marked change took place in the patient's condition. Diarrhea developed, and the woman was evidently suffering pain. On the 4th of February she was undoubtedly awake, and in the evening spoke in a hoarse whisper asking for a sour drink. This was the second time she had spoken in thirteen years. On the morning of the 5th of February again asked for a drink, yawned twice, and fell asleep again. In the afternoon was again awake, fed herself in an awkward way, and in the evening spoke again in a natural manner. I sent for her friends, and they endeavored to get her to take notice of them, but she did not appear to know them, and went to sleep as usual. The trained nurse's notes for the next few days are as follows:

*February 6.*—Will feed herself with bread or anything dry. Hand shakes too much to use a cup or spoon. Will ask for anything she wants, but will not speak at any other time. Always uses her left hand.

*February 7.*—I was called in about 4 A. M., and found her lying on the floor; she would not speak, but from all appearances no one had touched her; she had evidently gotten out of bed herself. At 9:30 A. M. she was cold and very pale; about fifteen minutes later her face was flushed and moist, body warm, hands, knees, and feet cold. This soon passed off, leaving her in her former condition. Temperature was 95.4°, lower than at 8 o'clock. This afternoon asked for a sour drink and a big cake. Spoke hurriedly, but quite loudly and distinctly. Kissed the nurse twice when asked to do so.

*February 9.*—Has not been well at all to-day. Moaned when disturbed. Has eaten scarcely anything, but has taken more milk than usual. Has had slight diarrhea since last Tuesday; worse to-day.

*February 11.*—Asked frequently for drinks to-day, and last night said her throat was burning. Does not appear to recognize any of her friends nor to realize that she is among strangers. So long as her wants are attended to she seems quite unconscious of anything else; not exactly unconscious either; but as though she took no interest in what went on around her.

*February 12.*—Is better this morning; had no diarrhea during the night. Has asked three times for something to eat, which sounds like meat, but when I get it for her she will not eat it.

*February 13.*—Diarrhea much worse to-day.

*February 15.*—Diarrhea somewhat better.

On the 16th she was slightly better, and asked for beer and cocoa, and said she felt as if she were burning up. From this time she steadily grew worse, and died on the 26th.

Dr. Ruttan, professor of chemistry, McGill University, made elaborate analyses of urine sent to Montreal from time to time, and without offering any detailed statement here, I may say that the general conclusions arrived at were as follows: The whole of the urine passed in six days was sent, and he says the total amount, if representing six days' urine, is about one-seventh the normal. This contains all constituents in about normal quantities in relation to the volume of the urine, except the phosphoric acid, which is about one-third what it should be.

#### AUTOPSY.

*Inspectio cadaveri.*—Nutrition poor; body much emaciated; apparent age 65 to 70; weight about 50; rigor mortis complete. Ante mortem staining on hands and feet; post mortem staining on back of trunk; bedsores on sacrum, tip, and ball of great toe; feet and ankles edematous; legs flexed on thighs by contracted tendons; no teeth, and jaws much absorbed.

*Sectio cadaveri.*—Head: Scalp thin and easily dissected; calvarium of average thickness; tables thin, however, diploë being in excess; dura mater not adherent to the skull, slightly opaque at vertex; one slight adhesion to brain at margin of longitudinal fissure; ante-mortem clots in longitudinal and lateral sinuses, the clots in the lateral sinuses being particularly well organized.

Brain: The brain weighed about 35 ounces; macroscopically, it was healthy in appearance; in fact in asylum experience I have never seen as healthy a brain in the post-mortem room. Convolution well marked and sulci deep; gray matter abundant; brain substance firm; ventricles free from evidence of disease; brain not examined microscopically.

Thorax: Substernal adhesions. Emphysema of cellular tissue beneath sternum; cartilages not ossified.

Heart: Small; weight, 3½ ounces. Pericardial fluid in average quantity; blood in great veins, and right auricle fluid; walls of right auricle and ventricle unusually thin; valves normal; small postmortem clot in left ventricle; walls of left ventricle hypertrophied; left auricle normal; valves of left side normal.

Aorta: Ascending aorta dilated into a fusiform aneurism; capacity about twice that of normal; arterial coats not thinner than normal; no evidence of atheroma; no pressure effects noticed; varicose veins on posterior walls of the heart; abdominal aorta atheromatous; antemortem clots in abundance.

Lungs: Right, very adherent at apex; small adhesions all over surface of lung; apex, a mass of tubercle; in fact, tubercles were found scattered throughout the whole lungs, and in the apex a small cavity existed; hypostatic congestion marked. Left, in this lung a certain amount of hypostatic congestion was apparent, and an occasional tubercle was found; otherwise the lung was normal; cord-like adhesions of pleura on surface.

Abdomen: Liver adherent to chest walls and diaphragm; whole capsule tore off in taking out and remained attached to diaphragm and abdominal wall; weight, 20

ounces; three vertical furrows present on anterior surface of right lobe; these furrows were about 2 inches in length; center one distinctly marked; nutmeg condition present.

Stomach: Large; about 2 inches from pyloric orifice was a constricted portion. This condition was undoubtedly not the result of any inflammatory action, but the natural shape of the stomach, giving rise to an appearance suggestive of a rudimentary second stomach.

Intestines: Small; evidences of an old peritonitis; adhesions everywhere; there were several constricted portions from 3 to 6 inches long; in no place was there complete stricture, and no scars were present; above the constricted portions the intestine was much distended.

Cæcum: Walls much thickened and much venous congestion; inner surface dark red, and roughened; had appearance of numerous varicose veins in wall.

Ascending colon: One portion constricted, and part preceding dilated; transverse colon, normal; descending, slightly dilated.

Kidneys: Right, very small, about  $2\frac{1}{4}$  inches long; apparently normal; left, about an inch longer than right; apparently normal; capsules non-adherent.

We may sum up the case by saying that in the subject under consideration we have a woman inheriting from parents an intensely neurotic organization, in consequence of which she showed many indications of an ill-balanced and unstable nature culminating in various vital crises, including periods of stupor. In fact, this woman seems to have spent nearly one-third of her whole existence in an unconscious condition, being then a purely vegetative organism. At one period of her life she was a veritable Rip Van Winkle, finally sinking into a long lethargy from which there was only a brief consciousness prior to the final stoppage of the vital mechanism. But it is to be noted this curious condition was not the result of any gross lesion of the brain, but of hidden molecular peculiarities, which renders the case to my mind all the more instructive when considered in connection with all those states I am now considering.

## II.

I propose now to discuss the real nature of hibernation and kindred states.

In the paper on squirrels, read before the Royal Society of Canada in 1887, I said, speaking of hibernation:

I think it is very probable that, when the matter has been fully investigated, all degrees of cessation of functional activity will be found represented, from the daily normal sleep of man and other animals, to the lowest degree of activity consistent with the actual maintenance of life.

As a matter of fact this is the conclusion toward which all my investigations since that time have tended. Though some maintain that in true hibernation there is cessation of respiration, it would be hard to prove this; for, as Hall showed, the circulation continues and the very beating of the heart against the lungs displaces a certain amount of air, and in any event we can not leave out of account diffusion of gases which in all cases of animals with lungs plays an essential part in the process of respiration. It would be interesting to know the condition of the heart in a hibernating frog or turtle, but in such creatures the skin, as also probably in snakes, has a respiratory function. Live frogs will stay for hours at the bottom of a tank in winter provided fresh water is flowing over them constantly. In fact, winter frogs kept under these conditions respire largely by the skin. So far as the bat is concerned it is difficult to observe any respiratory movements, but in the woodchuck I never fail to notice them at considerable intervals, say once in five to nine minutes, even when hibernating most profoundly. The respirations were peculiar. Sometimes one deep inspiration, preceded by a sudden relaxation of the enlarged chest, would be succeeded by a long pause; again, there would be a series of very slight respiratory movements. It was always possible by the respirations alone to predict when the animal was approaching the waking state. The awakening was never sudden, but gradual, often extending over hours. I have seen something like this, though less remarkable, in the bat. This is no doubt protective to the vital machinery, for when Hall maintained that bats suddenly awakened from the hibernating condition died speedily, he was in the main, if not entirely, correct.

A brief consideration of natural daily sleep will throw light on winter sleep. Sleep is favored by moderate exhaustion, a good condition of nutrition, and the

absence of all sorts of peripheral stimuli. The case of the youth having but one good eye and one hearing ear who could be put to sleep by closing these up is very instructive. This lad did not, however, continue to sleep indefinitely, but awoke after a number of hours, showing that though there are certain conditions in the environment that favor sleep, the latter is essentially a condition of the central nervous system and dependent on laws governing the latter. This view makes it clear that sleep is naturally a nocturnal condition for most animals, owing, no doubt, to the evolution of life in relation always to the environment. The fact is we can not conceive of life except in and by reason of, in a sense, some environment. The change of the seasons, day and night, and all the periodicities of the inorganic world have as a natural consequence stamped themselves on living things, plants as well as animals. Sleep, then, is essentially a rhythmic diminution of the activities of all the tissues, but especially of that one, which controls all others, the nervous. Rhythm seems to be at the basis of all things organic and inorganic, but has not been enough considered in our explanation of living cells. It was long the custom to explain sleep by anæmia of the brain, whereas the very anæmia was due to a contraction of the blood vessels of the part accompanied by the diminution of the heart beat, both of which are periodical and dependent on the rhythm of the nervous system itself. Of course, temporary anæmia of the brain favors sleep, though it is not the essential cause. As a natural consequence of the decline in the activity of the great controller of the cell activities (metabolism), i. e., the nervous centers, it is found that all the functions of the body, without exception, perhaps, are diminished during sleep. Marshall Hall and others since his time have shown that the gaseous interchange in a hibernating animal is greatly lessened. This diminished metabolism explains why the animal does not require to eat, or but little. It explains the diminished excretions, etc., etc. This being understood, it is not surprising that hibernating animals may be kept under water for long periods, as is the case with newly born mammals, as kittens and puppies, whose vital machinery as yet works very slowly, which are in fact in a condition but slightly more advanced physiologically than the uterine, which is a sort of a reptilian prenatal state, as regards the circulation and respiration.

As the metabolism of reptiles and amphibians is of a much slower kind than that of mammals it is not surprising that their winter sleep is more profound. But it is to be observed that the change from their most active to their most sluggish condition is not probably relatively greater than in the case of mammals. All forms of profound winter (or summer) sleep are protective, both of the individual and the species. Manifestly amphibia, reptilia, and other groups of the animal kingdom must have utterly vanished from the face of the earth but for such a power to adapt to conditions. Probably many individuals, if not some entire groups, have, through more or less complete failure to adapt, disappeared before this habit of the nervous system and of the whole organism became perfect enough. It is equally clear, from the investigation given to the subject, that hibernation, like daily sleep, is not a fixed and rigid thing, but just as it has been the result of adaptation to the environment by virtue of the plasticity of function of all living cells, so the power to modify still remains. It is possible to conceive of its being lost in certain groups of animals; indeed, this phase of the subject has been as much impressed on me as the other. Sleep, hibernation, and all such states are not invariable, but to a certain extent so dependent on the surroundings that, as in the case of my last marmot, also of turtles and frogs kept within doors, there may be an omission of that condition which is habitual under the normal environment of the animal.

I would like to emphasize these facts, for they seem to me to throw great light on the evolution of function at all events, and on those changes which may become so great as to lead, we can hardly say, to what, in the lapse of time. For years I have had turtles, and especially frogs, under observation during the winter months. Our frogs for laboratory use at McGill University are kept in a tank in which the water

is being continually renewed by a slow stream. They are not fed. None of the frogs seem to pass into a condition of true hibernation, but they descend to the bottom of the tank and remain quiet, as if asleep or partially torpid, as indeed I know they often are for hours. In this is an interesting modification of that most profound torpor which they experience when buried in the mud of ponds. Even in the winter life of a creature like the marmot we may have all degrees of drowsiness or torpor, as I have shown; and it is not to be forgotten that our own daily sleep has its degrees, so that the night's sleep may be represented by a curve with a sharp rise and very gradual fall, which may, as we all know, be greatly modified by circumstances. The same laws seem to apply to all the known cases of human lethargy, hibernation, sleep, or whatever the state may be called. In the case of the buried sheep and hogs the protective value of the condition is evident, as also in the case of the lethargic woman. This individual, with so ill-balanced and unstable a constitution, would probably have been carried off by some form of actual disease long before had she remained awake. She could exist as a mere vegetative organism, but not as a normal human being in the ordinary struggle for existence. One thing which has been much impressed upon me by my studies of this whole subject is the varying degrees of sensitiveness to temperature and meteorological conditions in different groups of animals and different individuals of the same group. The bat as compared with the marmot, for example, may be worked like a machine by varying the temperature. On the contrary, the degree to which the woodchuck is independent of temperature was a surprise to me after my experience with the bat. But the woodchuck answered like a barometer to predict storms; in fact, I am satisfied that many wild animals have a delicate perception of meteorological conditions which man has not, and which in a sense makes them wiser than our science and wiser than they know, for they act reflexly, as it were. Often my marmot would be heard in the night scraping the straw about him prior to a storm that did not reach us for many hours after.

Marshall Hall laid it down as one of the principal conclusions that in hibernating animals "muscular irritability" is increased. If the term reflex be substituted for muscular I believe the conclusion is correct. I found as a result of scores of trials that when the marmot was hibernating he was more sensitive to slight stimuli, such as blowing on the hairs of the skin, than when merely sleeping. Plainly this was not a case of muscular irritability at all, but it does indicate that the reflex mechanism is more excitable as it is, for example, in an animal under the influence of strychnine and as it is in animals from which a portion of the cerebrum has been removed. It may be because the unconsciousness is so profound, i. e., the brain so far from its ordinary functional activity, for it is well established that the brain inhibits the spinal cord normally to a certain extent. Apparently this increased reflex excitability must be to the advantage of a hibernating animal, for the cord and medulla oblongata are the parts of the nervous centers that especially preside over the functions of organic life which are necessary to maintain a mere animal existence. All problems of a biological kind must ultimately be referred to cells, and so with this of hibernation. Indeed, it would seem that unicellular animals pass into a condition which is related to that of hibernation. The so-called encysted stage of protozoa is perhaps analagous and similarly preservative of the individual and the species.

The study of a subject like the present one gives rise to many questions. Can the molecular machinery of life entirely stop and yet be set in motion again? We know that cold-blooded animals may be frozen and completely restored to a natural condition. This and the encysted condition of protozoa are suggestive of such a possibility. Yet in insects a condition of perfect quiescence is accompanied by the most wonderful changes. The wormlike caterpillar becomes within its cocoon the butterfly with locomotive powers immeasurably greater. For myself the more I study biological problems the less am I inclined to subscribe to rigid formulæ of

being. The study of a single group of animals from a physiological point of view, much less that of a single individual, does not suffice to enable one to lay down laws that will apply to similar processes in other groups of animals except in the most cautious way. I can never forget the lesson of my marmot that did not hibernate at all, and what modification of present views more extended study of this subject of sleep in all its phases will produce, it is impossible to say.

All my own studies have greatly impressed me with the plasticity of living things, their power to adapt themselves to altered environments; and if I might suggest one of the great changes that is likely to come over the biology of the future, it is a recognition of the above fact; so that we will cease to generalize so widely from such narrow data, or rather, perhaps, we will be ready to believe that phenomena very different from those we know may be possible in the realm of living things. It has often occurred to me that possibly if such considerations were kept in mind we should not be disposed to assume that the conditions under which life now exists are precisely those under which it always did exist. Would not a little more biological agnosticism help such sciences as geology and paleontology?

---

### PATHOLOGICAL ANATOMY OF YELLOW FEVER.

By JOSEPH JONES, M. D., LL. D.,

*Professor of Chemistry and Clinical Medicine, Medical Department Tulane University of Louisiana,  
Visiting Physician Charity Hospital, New Orleans.*

I shall now direct your attention to a subject of great importance to all students of medicine and of transcendent importance to the practitioners of medicine in tropical, semi-tropical, temperate, and insular America,—the pathological anatomy of yellow fever.

If you will examine carefully the systematic treatises in the theory and practice of medicine, you will find but little of value relating to the pathology of yellow fever; in fact, you will find the statement in some of your text books that “yellow fever has no pathology.” I shall deal solely with the results of my clinical studies, post-mortem examinations, and micro-chemical investigations of the past thirty years, and I feel assured that you will agree with me that yellow fever has a distinct pathological anatomy, wholly different from that of malarial fever, and as distinctively characteristic as the pathology of typhoid or enteric fever.

It is of the utmost importance that the Southern physician, as well as the practitioners in all the maritime cities, should be able to diagnose accurately the various forms of fever. The report of a case of yellow fever in any city within the bounds of the United States excites wide speculation. The people flee from the infected spots and rigid quarantines are rapidly instituted against the suspected locality. If an error is made in diagnosis, if it be not yellow fever, great damage results to the commerce and to the happiness of the suspected people. If, on the contrary, the disease be allowed to spread, through the failure of the medical profession and of the health authorities to correctly and promptly determine its existence, the epidemic may gain such headway that it can never be arrested and thousands of lives may thus be sacrificed. In the United States yellow fever is limited to certain months of the year and never prevails during the winter months. Even here in New Orleans the epidemics have been bounded by sharp lines. In Cuba, Havana especially, and in Mexico, Vera Cruz especially, the disease may prevail through the entire year.

I call your attention to the following table, which I have constructed for the purpose of illustrating the relations of yellow fever to climate in this city.

*Monthly deaths by yellow fever during a period of thirty-two years, 1847-1878.\**

| Year.      | May. | June. | July. | Aug.   | Sept.  | Oct.  | Nov.  | Dec.  | Total. | Date of first case.                                                    |
|------------|------|-------|-------|--------|--------|-------|-------|-------|--------|------------------------------------------------------------------------|

\* Reports of Joseph Jones, M. D., President of the Board of Health, State of Louisiana, 1880, 1881, 1882, 1883.

From the preceding table it is evident that, as a general rule, the great epidemics, as those of 1847, 1849, 1853, 1854, 1855, 1858, 1867, and 1878, commenced early in the hot months (May, June, and July), and attained their maximum intensity in August and September. Thus, during the period of thirty-two years the deaths from yellow fever in New Orleans were as follows: January, 6; February, 0; March, 2; April, 0; May, 5; June, 49; July, 2,248; August, 10,639; September, 11,346; October, 5,714; November, 1,177; December, 119. The curve of yellow fever, therefore, corresponds, to a certain extent, with the curve of temperature. Thus, from the records of thirty-eight years, which I have consolidated and calculated from the most reliable data, the mean temperature of New Orleans is as follows: January, 56.28°; February, 58.03°;

March, 64.27°; April, 69.41°; May, 75.90°; June, 81.35°; July, 83.21°; August, 83.14°; September, 79.64°; October, 70.27°; November, 62.80°; December, 56.43°. Averages: spring, 69.56°; summer, 82.53°; autumn, 70.75°; winter, 56.91°; year, 69.51°. The origin and spread of yellow fever, therefore, depends absolutely upon an elevated temperature, ranging from 70° to 85° F., and its decline depends upon a mean temperature ranging from 65° to 56° F. These figures, of course, relate to the mean or average monthly temperature, the extremes being much higher or lower, ranging during the year in New Orleans, as shown by meteorological observations extending from 1817 to 1878, from 17° F. to 100° F. Seaports liable to the infection of yellow fever should be carefully inspected and in the event of the appearance of the disease, the case or cases should be at once isolated and the surrounding houses, yards, and streets thoroughly cleaned and disinfected. Fight the enemy immediately on sight, vigorously, continuously, and with the best-known agents and appliances.

#### PATHOLOGICAL ANATOMY OF YELLOW FEVER.

*Exterior.*—Generally full and much reduced in flesh; features may even present a swollen and bloated aspect; skin of face and upper portions of trunk of a golden yellow color. The dependent portions of the body are of a mottled purplish and yellow ecchymotic appearance. Black vomit frequently oozes from the corners of the mouth and trickles down the face and neck. When the muscles are cut a large quantity of dark blood escapes, which, upon exposure to the atmosphere, changes to a bright scarlet hue. Putrefactive changes take place rapidly after death. In some cases of yellow fever, especially when the functions of the kidneys have been arrested for some time before death, the putrefactive changes take place with great rapidity and energy, and sometimes even appear to commence before death, the body exhaling a disagreeable odor.

*Cerebro-spinal nervous system; sympathetic nervous system.*—The post-mortem examinations of the brain, spinal cord, and sympathetic system have thus far yielded no characteristic lesions to which the aberrant nervous symptoms of yellow fever can be referred. Beyond congestion of the capillaries of the cerebro-spinal and sympathetic systems, which congestion appears to be referable to the same cause as that producing capillary congestion in the internal organs, I have observed no structural or hæmorrhagic lesions, as fibrinous effusion or softening of the cerebro-spinal and sympathetic nervous structures. Chemical analysis revealed the presence of urea, bile, and leucin in the brain, and the effects of these substances, as well as to the direct action of the yellow-fever poison, must be referred the aberration of intellect, the restlessness, convulsions, and coma.

The amount of congestion of the blood vessels of the brain will, to a certain extent, vary with this stage, and with the conditions under which the death takes place. Thus, when the functions of the kidneys are greatly impaired or wholly suppressed, owing to the retention of the watery elements of the blood, the vessels throughout the entire system are filled with blood to repletion, and the brain is, especially from its soft structure and the character of its circulation, the most affected. In such cases the blood is seen issuing from the cut surfaces of numberless vessels when sections of the brain are made. Under the microscope the three sections of the brain reveal a state of great hyperæmia, the minute capillaries being filled with colored blood corpuscles. The golden hue of the brain substance and membranes, as well as most of the tissues generally, is due to the presence of the coloring matter of the bile, and also to the escape of hæmatin from the blood vessels.

When death occurs after profuse hæmorrhages from the stomach and bowels the cerebral structures present less evidences of congestion than when these symptoms have been absent or present to a smaller degree. It is probable that the cerebral ganglia and commissures, as well as those of the spinal cord and sympathetic nervous system, are affected with the same chain of chemical reactions, which result in the formation and accumulation in the blood of oil, and also of this product in the

heart, liver, and kidneys. Fatty degeneration has been observed in the nuclei of the minute vessels of the pia mater venules, as well as arterioles. In many vessels the nuclei had disappeared, leaving fat globules in their places. With reference to the brain the most prominent observation thus far made is the existence of fatty degeneration of the blood vessels of the cortex cerebri, similar to that observed in the vessels of the pia mater, together with degeneration of the ganglionic bodies of the cortex. If these observations should be confirmed by further research, and especially by chemical analysis, determining the exact proportion of the oil in the brain in health and various diseased states, it will thus be shown that the nervous system, both cerebro-spinal and sympathetic, is involved in a similar series of changes as the other organs. The universality of these changes point to the blood as the great medium and source of the chemical actions and we have a confirmation of this view in the fact, which I have determined by chemical analysis, that the oleaginous constituents are greatly increased in the blood of yellow fever. That the mere presence of oil in increased amounts in certain organs during yellow fever is not the cause of the gravest symptoms is evident from the rapidity of the convalescence in many cases and also from the well-known fact that in many cases the general health is greatly improved by an attack of yellow fever. The gravest symptoms of this disease must be sought not merely in the structural alterations of certain organs, but in the initial chemical changes induced by the poison, and which precede the final lesions discernable after death.

*Heart:* Pale yellow and brownish yellow, as if undergoing fatty degeneration. Structures of the heart flabby and somewhat softened; numerous oil globules deposited within and around the muscular fibrillæ of the heart. The appearance of the heart in a case of yellow fever (Edward Griffin, who died in the Charity Hospital of yellow fever November 9, 1876, on the sixth day of the disease, after the ejection of large quantities of black vomit) is represented in the following colored figure (No. 1). Heart yellow and softened. Under the microscope transverse markings of muscular fibres indistinct, and much oil and granular matter deposited within and around the muscular fibres. The appearance of the muscular fibres of this heart are represented in Fig. 2. One thousand parts of the muscular structure of the heart contained water, 786.44; solid matter, muscular fibre, etc., exclusive of oil, 267.06; oil, 46.50. In this case the left ventricle was dilated and hypertrophied, but this condition appeared not to have affected the health of the patient before the advent of fever.

In the case of Samuel Rinsley, aged 23, who entered the Charity Hospital November 14, 1873, in the fourth day of an attack of yellow fever and who threw up black vomit on the 16th and 17th and who died at 1 o'clock P. M. on eighth day of disease, the autopsy was made eight hours after death. Weight of heart, 9 troy ounces; great congestion of blood vessels of pericardium, resembling the appearance of the pericardium of a case of yellow fever which died on the sixth day of the disease, August 5, 1871, represented in Fig. 3. The blood vessels of the heart were distended with dark-colored blood; the cavities of the heart contained about 3 fluid ounces of blood and golden-yellow clots; vena cavæ and pulmonary veins filled with fluid blood. When washed the muscular structures of the heart presented a distinct yellow color, similar to that of the heart delineated in Fig. 1, and was readily mashed between the fingers. Under the microscope the muscular fibrillæ presented indistinct transverse striæ and contained numerous oil globules and much yellow granular matter, resembling the fibres of the heart of a case of yellow fever depicted in Fig. 2. One thousand parts of the muscular structures of the heart contained water, 736.65; solid matter, exclusive of oleaginous matters, 186.80; oil, 76.59.

In the preceding case oil or fat was present in abnormal quantities in the muscular structures of the heart, the fat being deposited within and around the muscular fibrillæ in the form of minute globules of various sizes. There is also an obliteration or obliterations of the muscular fibrillæ of the heart, leading to a disappearance of the muscular striæ.

 $\frac{1}{16}$  inch objective Becks.*

*Fig. 3: Pericardium  
magnified 2 inch objective  
Death 6<sup>th</sup> day of disease.*

The removal of the particles of oil from the muscular structures of the heart by sulphuric ether did not restore the obliterated striæ, neither did this agent remove all the molecular particles, a portion at least being insoluble in ether, alcohol, and chloroform, and having an analogous constitution to albumin and fibrin. It would without doubt be a matter of great interest to medical science to establish clearly the exact physical and chemical changes which result in the final transformation of the muscular structures of the heart and secretory and excretory structures of the liver and kidneys into fat. The difficulties of such an investigation are very great, especially as the chemical research can be commenced only in fatal cases and after death. The complete investigation of this subject should embrace the following inquiries: (1) Is there an actual increase of the entire amount of fat in the blood organs and textures in yellow fever? (2) Is there any movement of the fatty matters from the positions in which they are chiefly accumulated in health, as in the adipose tissue, the marrow of the bones, the brain, spinal cord, and nerves generally, during the febrile stage of yellow fever? (3) Are the heart, liver, and kidneys simply infiltrated with fat conveyed by the blood during fever? (4) Is there an actual conversion of the fibrin and albumin of the blood and the albuminous elements of the heart? (5) Does the accumulation of fat in certain organs in this disease result from chemical changes directly excited by a specific poison, or from imperfect oxidation, or perverted nutrition? (6) Has the perversion and arrest of the functions of the liver and the retention in the blood of the constituents of the bile any relationship to the deposits of fat or oil in the various organs?

As the acute fatty degeneration of yellow fever is in nowise dependent upon the food of the patient during the fever, the change occurring with rapidity during absolute starvation, it is evident that the only possible sources of the oil or fat are those indicated in the preceding inquiries, namely, the preëxisting sources of fat in the transformation of the heterogeneous and albuminous constituents of the blood and organs. The cavities of the heart in many cases are filled with dark fluid blood, yellow fibrous clots sometimes present. The yellow-fever blood contains abnormal amounts of urea and extractive matters and ammonia.

By testing blood greatly diminished in amounts I have determined both by chemical analysis and microscopical examination that the heart undergoes fatty degeneration in yellow fever. As far as my observations have extended, the heart undergoes more rapid and extensive degeneration in yellow fever than in any other acute disease. The acute fatty degeneration of the heart in yellow fever should not be confounded with similar changes observed in spirit drinkers and in certain cases of chronic disease, but is more probably dependent upon the same or some chemical actions as those leading to a similar result in phosphorus poisoning and in typhoid and typhus fevers. In yellow fever the fat is deposited within and around the muscular fibrillæ of the heart in the form of minute globules of various sizes. There is also an alteration or degeneration of the muscular fibrillæ of the heart, leading to a disappearance of the striation. The removal of the particles of oil from the muscular structures of the heart by sulphuric ether does not restore the obliterated striæ, neither does this agent remove all the molecular particles, a portion at least being insoluble in ether, chloroform, and alcohol and having an analogous constitution to albumin and fibrin. Fatty degeneration of the heart is, therefore, not the sole state of this organ in yellow fever. The molecular change has taken place in the substance of the muscular fibers and this change affects the albuminoid or nitrogenous constituents, and most probably represents one of the stages of acute fatty degeneration. The pericardium in yellow fever presents a congested appearance. Under the microscope the minute blood vessels appear to be congested with colored blood corpuscles. The pericardial fluid is of a deep yellow color. The appearance presented by the pericardium of a case of yellow fever which terminated fatally in New Orleans August 5, 1871, is represented in Fig. 3. The pericardium was put upon a glass slide and

preserved in Canada balsam. The drawing represents the natural appearance as injected with blood.

*Lungs:* Dependent portions greatly congested, otherwise normal. In some cases circumscribed effusions of blood in structures of lungs. I have in a few instances observed pneumonia as a supernumerary disease in yellow fever. In such cases the sputum consisted of almost pure blood. The supervention of pneumonia causes a continuation of the febrile phenomenon beyond the usual period of the uncomplicated disease.

*Stomach:* Mucous membrane of the stomach in many cases internally congested, softened, and eroded. Stomach often contains large quantities of black vomit. Reaction of black vomit often alkaline, from the presence of ammonia, resulting from the decomposition of urea, eliminated by the gastro-intestinal mucous membrane. Ammonia and urea present in the black vomit ejected during life, and also when examined almost immediately after death. The presence of ammonia in the stomach and black vomit was not the result of post-mortem putrefactive changes. In many cases ammonia was present in such large amounts that when a rod dipped in hydrochloric acid was held over the mucous membrane of the stomach or over the black vomit, dense fumes of chloride of ammonium were found, as if the rod had been held over a bottle containing liquid ammonia. Chemical analysis revealed the presence of ammonia, and also of urea in the black vomit. Under the microscope the black vomit is seen to contain colored blood corpuscles, and cells of the mucous membrane of the stomach, and broken capillaries. In some cases fungi and fibrin were numerous in the black vomit, in others they were absent.

That the stomach suffers and suffers severely in yellow fever is evident from the fact that in the great majority of cases the stomach is finely injected with blood and exhibits, even when examined immediately after death, abrasions of the mucous membrane in pit-like folds and furrows. In some cases the whole surface of the stomach is affected, and in others the effusion and injection is confined to the cardiac or pyloric portion, but in some rare instances the stomach, duodenum, and intestines have been said to present an almost entire absence of apprehendable lesions. I have not myself, in post-mortem examinations, observed the absence of lesions in the gastro-intestinal mucous membrane. The congestion of the stomach is to a certain extent due to the disturbance of the circulation in the line, but not wholly to this cause. We must, after careful chemical and microscopical examination, admit the existence of irritation, desquamation, and hæmorrhages.

The congested appearance of the mucous membrane of the stomach after death from yellow fever is represented in Figs. 4 and 5—Charity Hospital, October, 1871, and Charity Hospital, November, 1876. These illustrations must be regarded as exhibiting the extreme conditions of congestion in the mucous membrane of the stomach in yellow fever. In many cases the stomach after death presents less congestion, and in some portions of the mucous membrane different degrees of congestion are manifested, being much greater in some portions of the mucous membrane of the stomach than in others.

*Intestines:* As a general rule these viscera are dark colored and distended with gas. In some cases the reaction of the intestinal contents was strongly alkaline from the presence of ammonia. Hæmorrhage from the intestinal mucous membrane has been observed during life, and in such cases, as well as in others in which no blood has been discharged previous to death, the intestines have been found, in post-mortem examinations, distended with blood. A remarkable feature in yellow fever is the frequent occurrence of intussusception of the small intestine. The quantity of intestine invaginated sometimes exceed a quart. The large intestine and the lower portion of the small are not so often found congested as the stomach and duodenum, yet such a condition is by no means rare. Congestion of the veins, venules, and mucous membranes generally in yellow fever has been referred to the anatomical distribution of the veins, which like those of the stomach are tributaries to the portal veins,

but we have been inclined in many cases to regard the congestion as active and not passive. During life the rectum in yellow fever presents an intensely red and congested appearance, and some cases of yellow fever in 1878 were followed by irritation and fissure of the rectum.

The demonstration which we have given, illustrating the changes of the nervous structures and of the heart, blood, and alimentary canal, under the action of the yellow-fever poison clearly establishes the fact that yellow fever has a distinctive pathology. It is necessary that we should pursue this subject to the end, and indorse our proposition by an appeal to the results of microscopical and chemical investigations of the pathological lesions of other organs, as the liver and kidneys in yellow fever. An accurate comprehension of the pathological anatomy of the liver in yellow fever is especially important, as we are enabled to establish in the clearest manner the most marked differences between the pathological anatomy of yellow and malarial fevers.

*Liver:* Yellow in color and bloodless, resembling this organ in fatty degeneration, but firmer and denser in structure. Fig. 6 presents the general appearance of the yellow-fever liver. The specimen was taken from a subject in the Charity Hospital in 1871. Fig. 7 illustrates the appearance of the liver in a case of cirrhosis, induced by spirit drinking, which died in the Savannah Hospital in 1856; there was not only cirrhosis, but also fatty degeneration in this case. Fig. 8 represents the appearance of the liver in a case of yellow fever ingrafted on malarial fever. Fig. 9 represents a portion of a section of the liver figured in No. 7, magnified, showing congestion of portal capillaries with pigment deposits, and the yellow, fatty, and degenerated central portions of the lobules of the liver. Fig. 10 presents the appearance of the liver in yellow fever ingrafted on malarial fever. The black, pigmentary matter alters the yellow color characteristic of the yellow-fever liver.

The preceding figures, representing the appearances of the liver in yellow fever, should be compared with the following figures representing the appearance of the liver in malarial fever. Fig. 11, appearance of the liver in the acute stage of malarial fever, bilious remittent. Fig. 12, appearance of the liver in malarial fever of longer standing. Fig. 13, appearance of malarial liver loaded with pigment particles. Fig. 14, section of malarial liver, showing pigment deposit, magnified by 1 inch objective, 1871. In all the different forms of malarial fever—intermittent, remittent, and congestive—which have continued longer than five days, and in which there have been no previous alterations of the structures, as in cirrhosis and fatty degeneration, I have found the exterior of a slate and the interior of a bronze color, as shown in figs. 11, 12, 13, and 14. Fig. — represents a magnified portion of the section of a malarial-fever liver, showing a deposit of pigment chiefly in the portal capillaries in the periphery of each lobule.

Under the microscope the textures of the yellow-fever liver are infiltrated with much oil. The secretory cells of the liver are thus shown by microscopical examination to contain much oil. The liver of uncomplicated yellow fever, as far as my observations extend, and according to the observations of Louis and many others, is of a bright yellow color. It is probable that this color, as in the case of the malarial liver, varies with the length of the attack and the effects of previous diseases. Thus, Dr. Samuel Jackson, of Philadelphia, found the livers of those who had died in the early stages engorged with blood. The ducts of the yellow-fever liver are of a golden yellow color, while those of the malarial liver are of a brownish-yellow color. The golden yellow color of the yellow-fever liver can be abstracted both by alcohol and water. The yellow-fever liver is firmer and harder than that of malarial fever, contains much less blood, and is much less readily acted on by liquor potassæ and mineral acids. Liquor potassæ readily dissolves the malarial-fever liver, the decoction presenting the appearance of venous blood, while no such effect is produced by this alkaline solution upon the yellow-fever liver.

Chemical analysis reveals the presence of urea and fat in abnormal amounts. Animal starch and grape sugar are also present in the yellow-fever liver. As a general rule, grape sugar is absent from the malarial liver. In some cases the deposit of oil is confined to certain portions of the lobule, and may even differ in amount in different portions of the liver; but in the majority of cases the fatty infiltration and fatty degeneration of the protoplasm of the hepatic cells extends throughout the whole organ. The oil is deposited both within and around the hepatic cells. Fig. 15 gives the appearance of the hepatic cells and oil globules in the liver of yellow fever (case of Griffin, November, 1876). This figure should be compared with Fig. 16, representing the appearance of hepatic cells and pigment particles in the liver of malarial fever. Careful observations of the relations of malaria to yellow fever, and an extended examination of the statement of various observers, have convinced me that the apparent contradictory statements made by various observers, as to the presence or absence of the yellow color of the liver, which Louis regarded truthfully as the characteristic lesion of the disease, has arisen from two sources, namely, errors of diagnosis and failure to detect the preceding concurrent and subsequent action of malaria on this organ. In uncomplicated yellow fever, fragmentary particles, so uniformly present in the malarial liver, are uniformly absent. When yellow fever is engrafted on malarial fever, the preceding changes brought by the paludal poison alter and mask those developed by the yellow fever. Hence, the mingling of the yellow color of acute fatty degeneration with the dark bronze and slate of the malarial liver may produce a color very closely resembling the Spanish brown of the healthy liver. Careful scrutiny and examinations of the organs under the microscope will reveal both the oil globules and pigment particles. The distinction has been made by pathologists between fatty degeneration and fatty infiltration, the first being a process of true degeneration, with a tendency to the disintegration of tissue; the latter we observe as a simple definition of fat, in various cells and tissue, without any chemical alteration of their constituent elements. In fatty degeneration there is a conversion of the protoplasm of the cells into fat, which accumulates in the cell body, and as the albuminoid principles disappear they are replaced, *pari passu*, by fatty particles. It is thus assumed that the nitrogenized albuminoid and proteid particles are converted into fat. The fat is usually present in the cell in very small particles or droplets, and these may coalesce and form larger drops. The protoplasm may even be almost entirely replaced by fat. In fatty infiltration cellular protoplasm is displaced; in fatty degeneration it is replaced; in the former the corpuscular organisms suffer mechanically; in the latter the cells suffer chemically, and are ultimately destroyed. Fatty infiltration of cells is a common occurrence in the normal as well as pathological condition; but in this case the fat appears to originate outside of the cells and simply accumulates in them, causing a passive atrophy of the protoplasm.

In general, the fat droplets are larger in fatty infiltration than in fatty degeneration, and yet to this there are many exceptions. In spite of the differences just considered, it is often practically impossible to separate one process from the other micro-chemical tests, and histological appearances are not always sufficiently reliable for exact differentiation. The efforts of some writers to discard the terms "fatty degeneration" and "fatty infiltration," and to substitute the words "fatty metamorphosis," simply expresses the theory that the two processes are one and the same. In the case of the liver, both, in health and in disease, we meet with great difficulties in separating the two processes. Fatty infiltration may occur as the efforts of the excessive ingestion of oleaginous food, in chronic alcoholic, phosphorus, and arsenic poisoning, in certain exhaustive diseases accompanied by malnutrition, and in pulmonary phthisis, chronic dysentery, and in various conditions which are not fully understood. Fatty degeneration of the liver in many cases can not be morphologically distinguished from fatty infiltration. The fat is believed to be

From Nature by JOSEPH JONES, M.D.

Illustrating the pathological anatomy of specific contagious yellow fever. Comparison between ordinary fatty degeneration of the liver, and fatty infiltration of the liver in yellow fever. Section of the gastric mucous membrane in yellow fever. Fig. 17 represents a magnified thin section of a fatty liver, in a moderate degree of advancement of fatty degeneration. The cells containing oil are seen to be distributed for the most part at the periphery of the lobules, in the vicinity of the branch of the portal veins. Fig. 19. Section of a yellow fever liver magnified 275 diameters, showing the presence of oil globules. The capillaries still contain blood corpuscles. The group of cells above the figure represent the hepatic cells undergoing fatty infiltration and degeneration. Fig. 18. Section of a yellow fever stomach, showing the congestion of the veins, the infiltration of hæmoglobin, and the extravasation of blood caused by a rupture of the minute veins or larger capillaries. The glandular (A) and muscular layer (B) of the mucous membrane, and the subcutaneous connective tissue (C) are shown. The congested vessels descending through the glandular layer represent those straight vessels formed by the various radicles arising from the network of large capillaries beneath the epithelium, and surrounding the orifices of the gastric glands. The dots seen throughout the muscular layer represent transverse sections of muscular fibrillæ (magnified 50 diameters), after H. D. Schmidt, M. D.

formed by a transformation of the protoplasm of the liver cells. The fat droplets are, for the most part, very small and abundant, though this is by no means constant. Fatty degeneration of the liver cells frequently follows, and is associated with cloudy swellings in the varying conditions in which they occur, or it may appear in profound anæmia, and in the exhausted condition of the human system consequent upon the prolonged action of the malarial poison.

The accumulation of fat in yellow fever appears to be due both to the degeneration of the protoplasm of the liver cells and to infiltration of fatty matter. My researches upon the fatty degenerations of the liver in yellow fever have led to the following conclusions: (1) The muscular tissues of the heart show under the microscope, and under the proper chemical tests, rapid molecular change and fatty degeneration; (2) the liver cells exhibit rapid degeneration of the protoplasm of these cells and rapid increase of fat; (3) the albuminoid elements of the blood undergo rapid degeneration and rapid transformation into fat, under the action of the yellow-fever poison; I use the term "rapid" in contradistinction to the slow process of the development of fat in the normal condition; (4) it follows from the preceding propositions that the accumulation of fat droplets in the heart and liver in yellow fever may arise from a chemical change of the albuminoid protoplasm of the blood and of the cells; (5) the increment of fat (oil droplets) in the blood in the heart and in the liver of yellow fever is due to the direct chemical action of the poison of yellow fever in the albuminoid protoplasm; (6) the fatty degeneration caused by the yellow-fever poison ceases with the cessation of the action, and elimination and destruction of the morbid agent.

The degeneration of the protoplasm excited by the yellow-fever poison is temporary and not permanent; (7) if the fatty degeneration caused by the yellow-fever poison were permanent, and if the changes thus induced by the yellow-fever poison were an abiding and progressive degeneration, we would witness the effects, and the continuous and destructive effects, of fatty degeneration of the heart tissue as the sequelæ to many cases of yellow fever. In our experience such effects are readily traceable to the yellow-fever poison.

*Gall bladder:* The gall bladder in yellow fever is, as a general rule, contracted, flaccid, small, and contains little or no bile. The amount of bile does not generally exceed 100 grains. In malarial fever, on the other hand, the gall bladder is, as a general rule, distended with dark greenish black bile. In yellow fever the vomiting is rarely bilious, unless in the commencement of the disease, and the black vomit contains little or no biliary matter. The small intestines are rarely, if ever, discolored by bile in yellow fever, while in malarial fever it is common to find the gastric mucous membrane discolored by bile. I have observed cases in which the gall bladder contained only a serous liquid coagulable by heat. In two cases a decided hæmorrhage had taken place into the gall bladder, which was distended with black blood. The bile in yellow fever contains numerous cells from the mucous membrane of the gall bladder and casts of the hepatic ducts.

*Spleen:* As a general rule this organ is but slightly enlarged; in many cases normal in size and appearance. In many cases of yellow fever the spleen is neither enlarged, softened, or altered in appearance either upon the exterior or within. There appears to be no special alteration or destruction of the colored corpuscles in the spleen of yellow fever as in that of malarial fever. The enlargement of the spleen in fevers does not, from these observations, depend upon the diminution of fibrin, because this element of the blood is diminished to a much greater extent in yellow fever than in malarial fever, and at the same time the spleen is enlarged to a greater and more marked degree in the latter. Another fact worthy of consideration in this connection is, that in yellow fever the blood corpuscles are not specially diminished in amount, while in malarial fever they are rapidly destroyed, and this destruction seems to be greater in the liver and in the spleen. In malarial fever both these organs are loaded with altered blood corpuscles and with the pigmentary granules

resulting from the alteration of the colored blood corpuscles, while neither the spleen nor the liver in yellow fever afford any evidence of the alteration of the colored blood corpuscles.

*Suprarenal bodies:* These bodies appear to be subject to similar changes with the liver and the heart, and oil is increased in amount in the cells of the cortical and medullary substances.

*Kidneys:* These organs in yellow fever as a general rule present a brownish-yellow color, much lighter than that of health. The kidneys, in common with the heart and liver, contain much free fat. Fig. 20 represents the appearance of the kidney in yellow fever, and Fig. 21 represents the appearance presented by a section of the same kidney. These figures may be regarded as representing the more decidedly morbid kidneys in this disease, for in some cases they present greater degrees of congestion and deeper coloration from the presence of blood in the capillaries.

In the case of Griffin, who died of yellow fever in the Charity Hospital November 17, 1876, sections of the kidneys, made with Valentine's knife, revealed under the microscope increase of oil globules and granular matter. Many of the tubuli uriniferi presented a thickened and altered appearance, as if undergoing the changes characteristic of cirrhosis. One thousand parts of the kidneys contained, water, 800.33; solid excretory, molecular, and fibrinous matter, 158.39; oil or fat, 40.88.

In the case of Samuel Kingsley, who died of yellow fever in the Charity Hospital, November 17, sections of the kidneys under the microscope presented the appearance usual in yellow fever, namely, Malpighian corpuscles, tubuli uriniferi filled with oil globules, yellow granular matter, and detached excretory cells. One thousand parts of these kidneys contained water, 798.90; golden-colored oil and fat, 57.77; cellular tissue, bloodless excretory structure, etc., 143.33. When these sections of the kidneys are examined under the microscope, the Malpighian corpuscles and tubuli uriniferi are found to be filled with granular albuminoid and fibroid matter, detached excretory cells, and oil globules.

As far as my observation extends, these structural alterations of the kidneys have escaped the notice of preceding observers. The importance of these changes in the kidneys can not be overestimated, for upon them apparently depends the suppression of the urinary excretion, which is an almost universally fatal symptom. The changes in the kidneys may depend on some causes, among which may be mentioned as of prime importance, the alterations induced in the albumin and fibrin of the blood by the febrile poison, and the congestion of the capillaries, caused by derangement of the vasomotor system of the nerves, and by the altered blood. This condition of the kidneys is preceded by capillary congestion, as has been shown by the results of post-mortem examinations at different periods of the disease. The same observation applies to the liver. The fatty degeneration and structural lesions are presented by hyperæmia; but neither in the kidneys nor in the other organs can the mere stagnation of the blood in the capillaries be regarded as the prime cause of the subsequent degeneration or disintegration of the textures, and more especially of the secretory cells. The chief cause is the action of the yellow-fever poison on the blood and textures. The yellow-fever poison excites a train of chemical changes, the final result of which is fatty degeneration. Thus, in the case of the muscular fibres of the heart, there is fatty degeneration, although from the structure and action of this organ there could be no such passive congestion as we have in the liver and kidneys. It is probable that the fatty degeneration extends to all the unstriped muscular fibres, and may even disable the muscles of locomotion and animal life. The granules of the cells of the epithelium of the uriniferous tubules, set free by the disintegration of the protoplasm, oil globules, detached cells, and albuminous matters and mucus, form opaque granular masses which block up the tubuli uriniferi. We have in these structural alterations of the kidney, which vary in kind and degree according to the stage of the disease, an explanation of the fre-

FIG. 22.

PATHOLOGICAL ANATOMY OF THE KIDNEY IN BRIGHT'S DISEASE AND YELLOW FEVER.

quent occurrence of albumin, casts, detached cells of the epithelium of the uriniferous tubules, and oil globules and granular matter in the urine of yellow fever.

Fig. 22. Inflammatory division of Bright's disease. Bright's disease, first stage. Section of inflamed kidney, Bright's disease. Tubules with epithelium in situ with cloudy swelling, well shown in transverse section, Malpighian body large and opaque, magnified 450 diameters. The inflammatory form of Bright's disease may be divided into three stages, each characterized by very distinct anatomical characters: (1) that of inflammation; (2) that of fatty transformation; and (3) that of atrophy. Fig. 22 represents an enlarged view of the tubules (450 diameters) in the stage of inflammation in Bright's disease. In this stage the kidney is of normal size, or somewhat larger; its capsule is unaltered, and strips off readily; its surface is smooth, more or less congested, often pink; it is sometimes of a dark purplish color, sometimes mottled, pale, and purple. On section the cortical surface is relatively increased in volume. It is often congested, the Malpighian bodies standing out prominently from the surrounding tissue and the congested vessels separated by a varying amount of white (somewhat opaque deposits, composed of the altered tubules). The vascular spaces between the cones and the cortical substance are uniformly distended with blood; the cones are usually redder than the cortical substance, and from the engorgement of these vessels, and the altered condition of these tubules, they present a series of alternating red and white lines converging to the apex of the cone, at which point the white distinctly predominates. The pelvis of the kidney is natural. On microscopic examination with a low power, the congestion of the vessels and the alteration of the tubules becomes more distinct; the vessels are for the most part engorged with blood. The Malpighian bodies appear as if injected with red material, or, what is more common, they appear dense and opaque, of an ashen gray color. In the earliest period of the inflammation the former condition occurs; in the more advanced period, the latter. Many of the tubules, especially those of the cortical substance, appear darker and denser than natural; they sometimes appear as solid bodies, sometimes as tubes, with thickened and somewhat opaque walls. In the groups of tubules passing down toward the cones, and in the cones themselves, individual tubules here and there are affected like those of the cortical substance, and contrast strikingly with their neighbors which are unaffected. On examination with a power of from 300 to 400 diameters, the Malpighian bodies appear dense and granular, and when the tubes expand to receive the tuft of vessels, swollen and granular cells may be seen. The tubules are more bulky than natural, their epithelium is swollen, granular and dense, the cell wall indistinct, and the nucleus frequently imperceptible. On examining a transverse section the enlargement of the epithelium becomes very apparent, for the cells are large and granular, and the lumen is greatly reduced or altogether lost. In the tubules, so altered, a transparent homogenous material is frequently seen, which fills up the lumen of the tubes, and binds together, so to speak, and cakes into one mass the epithelium of these tubules; not unfrequently blood corpuscles are associated with this exuded matter, as is shown in Fig. 22.

Fig. 23. Bright's disease. Inflammatory form second stage. Section of kidney in second stage, inflammatory form, showing the fatty opacity in the tubules and Malpighian bodies. Fatty tubules and Malpighian bodies in stage of fatty degeneration magnified 350 diameters.

In the stage of fatty degeneration or transformation, to which term "large fatty kidney" is commonly applied, the inflammatory process has passed away, or, as is more common, has become chronic. But its effects remain. The organ is enlarged; the capsule is natural, easily stripped off; its surface is smooth, or slightly depressed here and there. It is pale and fatty in color and on its surface stellate vessels are frequently conspicuous. The color is peculiarly mottled from the mingling of opaque sebaceous-looking fatty portions with the whitish, more translucent tissues natural to the organ. On section the cortical substance is pale, of a yellowish-white color,

and increased in volume, while the cones are pink, and of natural color and size. The Malpighian bodies do not project prominently, as in the first stage. On closer inspection the sebaceous-looking parts may be seen to correspond to distended convoluted tubules, and not infrequently lines of this material may be seen running between the small arteries toward the cones. On microscopic examination with a low power (50 diameters), the tubules are seen in many parts distended with a black untransparent material; this is most marked in the convoluted tubules, but in the straight tubules, here and there, individuals or groups may be found affected. The Malpighian bodies are enlarged, but not prominent, and while they may be finely granular never present any black appearance of the tubules. Under a high power (300 to 400 diameters), the distended tubules are found to be filled with fatty granules, which for the most part are contained within the walls of epithelial cells, which again are embedded in a material that blocks up the tubules. The tubes, however, are found to be irregularly distended, in some parts much dilated and in others narrow and of the natural caliber. In the Malpighian bodies oil and fatty cells are frequent, but the capillary tuft is unchanged. The parts in which the fatty condition is revealed by the microscope correspond to those in which the dense-looking material is seen by the naked eye, as in Figs. 22 and 23.\*

Fig. 24, a vertical section of a yellow-fever kidney from near the surface. (a) Albuminoid cylinders. The epithelium of the uriniferous tubules, the basement membrane, and the granules embedded in its albuminous substance, are also displayed, magnified 275 diameters.† Fig. 25, fine uriniferous tubules containing different kinds of infarctions of the yellow-fever kidney. (a) Albuminoid cylinder with epithelial cells, and the remaining fragments of broken-down cells embedded in the albuminoid substances; (b) epithelium; (c) basement membrane; (d) empty portion of the tubule with cellular tissues; (e) remains of nuclei and cells magnified 235 diameters.

In the yellow-fever kidney we observe a degeneration of the protoplasm of the epithelial cells lining the uriniferous tubules. This degeneration of the protoplasm of the renal excretory cells is, without doubt, preceded by hyperæmia; but this hyperæmic condition of the renal capillaries must not be regarded as the primary or the sole cause of this condition. The primary cause is to be found in the action of the septic agent or ferment of the specific contagium of yellow fever upon the protoplasm of the blood and of all the active cells of the organism, including those of the liver and the heart.

In fatal cases of yellow fever the hyperæmia of the renal vessels has become greatly diminished at the time of death by the degeneration of the protoplasm of the excretory structures, by the loss of blood through the stomach and bowels, and by the slow but progressive accumulation of the great mass of blood in the large central blood vessels during the last hours of life. When death occurs in the active stages of malarial fever the kidneys, on the other hand, presents, most generally, a hyperæmic condition and are without the fatty degeneration of the parenchyma, so strongly marked in the yellow-fever kidneys. The degeneration of the kidneys taking place in the renal parenchyma during yellow fever does not resemble in all respects the fatty degeneration of the kidneys observed in parenchymatous nephritis.

A number of infarctions found in the uriniferous tubules during the course of yellow fever represent albuminous cylinders, while others consist of the remains of disintegrated epithelial cells, or are composed of both. They are met with in all portions of the uriniferous tubules, and vary in thickness in correspondence with the diameters of their canals. The largest are found in the convoluted portions, the so-called tubuli contortæ, and in the intermediate canals, which they frequently fill up through their entire length; in the descending and ascending body and in the collecting tubules they are generally smaller. The number of these casts and the

\* Bright's disease of the kidneys. J. George Stewart, M. D., F. R. S., 2d ed., p. 12-16.

† After H. V. Schmidt, M. D.

extent of their function, as well as the extent and nature of the pathological changes of the kidneys, will depend upon the length and relative severity of the disease.

*Urinary bladder:* As a general rule the bladder contains little or no urine in yellow fever. The urine is of a light yellow color, without any crystalline bodies, and loaded with albumin, granular fibroid matter, urate of ammonia, casts of the tubuli uriniferi and excretory cells of the kidneys. In some cases the urine is entirely suppressed for as long a period as forty-eight hours before death. So long as the kidneys perform their functions freely and regularly the patient may recover, even though black vomit may have appeared; but if the action of the kidneys has been arrested by structural changes, death is inevitable. The mucous membrane of the bladder is often congested, and in some cases ecchymotic.

---

### THE NUMBER OF THE RED GLOBULES.

By Dr. JOSE G. HERNANDEZ,

*Profesor de la Universidad de Caracas.*

The classical works on physiology fail to mention the influence of latitude upon the number of red corpuscles. The author has endeavored to study this question in the tropics. He started to find the physiological mean of the number of red corpuscles in the habitants of Caracas. The latitude of the city and elevation above sea level are given. Healthy individuals, medical students between the ages of 16 and 20 years, were chosen. Twenty-five counts were made with the apparatus of Nachet. The mean obtained per cubic millimeter was 3,247,000. The minimum was 1,900,000, and the maximum 3,840,000. The amount of urea secreted in twenty-four hours was also investigated in six cases, obtaining a mean of 21 grammes, with extremes of 15 and 25 grammes. This oligocythæmia is explained by the theory that the function of the red-blood cells is respiratory and that the process of oxidation is necessary to keep up the bodily temperature, a function that must be less active where the surrounding temperature is uniformly high. The diminished oxidation of the tissues results in a diminished secretion of urea. The statement, often repeated, that the climate of the tropics is a producer of anæmia, is thus confirmed.

---

### LA FORCE MUSCULAIRE CHEZ LES INDIENS.

Par le Dr. J. B. DA LACERDA, Rio de Janeiro, Brazil.

L'on croit généralement que les Indiens sont pourvus d'une très grande force musculaire. Nous avons eu une excellente occasion de vérifier combien était inexacte cette supposition. Pendant l'exposition anthropologique de 1882, à Rio, ce sont réunis, au Musée National, des représentants de diverses tribus, arrivés de l'intérieur du pays. Sur eux nous avons institué des expériences nombreuses et répétées, par suite desquelles il nous est resté la conviction que les Botocudos et les Cherentes ont une force musculaire inférieure à la moyenne des individus adultes de la race blanche et de la race noire. Nous avons employé le dynamomètre de Mathieu pour enregistrer la force musculaire; et nous ne l'avons enregistrée qu'après une longue série d'essais. Les plus forts des Indiens n'ont pu emporter l'aiguille au-delà de 120.

Sous le point de vue du développement des muscles il est encore notable l'infériorité de ces Indiens, comparés aux nègres. Leur agilité est à peine remarquable pour certains groupes de muscles, longuement éduqués dans l'exercice de certains actes qui font pour ainsi dire une partie intégrante de leur vie sauvage. C'est pour cela qu'ils sont très agiles dans le maniement de l'arc. En dehors de ça, ils ont des mouvements lents, paresseux. Nous n'avons pu essayer sur eux la course; malgré cela nous ne doutons pas qu'il seraient aisément vaincus par le premier venu d'autre race.

Leur mémoire auditive, en ce qui se rapporte aux sons musicaux est d'une infériorité extrême. Ils n'ont pas arrivé jamais à retenir une phrase musicale des plus simples, même après avoir été répétée devant eux une dizaine de fois.

Ils sont peureux lorsqu'ils connaissent le péril; de plus ils comptent davantage sur la ruse que sur le courage.

## SUR LES TROUBLES FONCTIONNELS DUS À LA CHALEUR.

Par le Prof. J. B. DA LACERDA, Rio Janeiro, Brazil.

C'est assez important pour nous, habitants des pays chauds, de savoir comment agit la chaleur sur l'organisme, et de quelle nature sont les troubles fonctionnels qu'elle produit. A ce sujet nous avons des expériences commencées il y a déjà quelques années avec la collaboration de mon regretté collègue, le Dr. Couty, et qui sont restées inédites. Nous en allons faire un résumé, qui doit être présenté au Congrès.

Les anciennes expériences de Cl. Bernard ont été trop artificielles; elles ont été faites dans des conditions qui ne sont pas celles de la nature. Nous n'avons pas eu recours aux étuves, et nous en avons eu pas même besoin, parce que nous pouvions profiter de la chaleur naturelle. A Rio, durant l'été, nous avons souvent dans la journée des températures variant entre 30° et 36° C., les effets de la chaleur étant encore accrus par la saturation hygrométrique de l'air et les calmes de l'atmosphère.

Quand ces conditions sont réunies, on sent une défaillance considérable des forces musculaires; l'activité nerveuse reste abattue; la peau sécrète énormément; les reins tarissent; le cerveau sommeille.

Nous avons cherché savoir dans quel état se trouvait la circulation, et quelles modifications se passaient dans l'activité des nerfs sous le coup des grandes chaleurs, en faisant des expériences sur les animaux.

En prenant la tension artérielle sur les chiens, avec des températures variant entre 30° et 35° C., nous avons toujours trouvé la tension très basse. Celle-ci variait entre 12 et 15 cent. c. de mercure, tandis que dans l'hiver la tension était entre 19 et 21 cent. c. de mercure. Deux facteurs physiologiques nous ont paru contribuer pour ce résultat; la dilatation paralytique des vaisseaux périphériques et l'affaiblissement du cœur.

Une étude, aussi comparative, appliquée aux nerfs, nous a fait constater que ceux-ci, actionnés par la chaleur, étaient devenus trop épuisables. Après quelques excitations graduées de la machine électrique, ils restaient inertes. Il fallait alors attendre quelques minutes pour voir les nerfs réacquérir leur excitabilité perdue.

Nous avons aussi étudié les effets de l'insolation. Les chiens exposés au soleil, immobiles, ont crevé au bout de 50 minutes tout au plus. Les troubles du commencement ont été d'excitation: accélération cardiaque, respiration pressée; pupilles rétrécies; abondant écoulement de salive. Cela durait une quinzaine de minutes. Ensuite il commençait la période paralytique: le cœur s'affaiblissait beaucoup; les pupilles étaient larges; l'écoulement de la salive cessait; la respiration s'arrêtait pour recommencer après. Lorsque la température rectale arrivait à 44° centigrades le moment de la mort était près. Celle-ci venait par arrêt respiratoire définitif, le cœur continuant à battre, sans pousser, pendant encore quelques secondes.

Tout de suite après la mort on constatait la perte de contractilité des muscles, du moins pour les muscles respiratoires et pour le cœur. Le sang était noirâtre, assez fluide; le cœur portait des taches hémorragiques sous l'endocarde; les poumons étaient engoués avec des plaques hémorragiques parsemées. Sous la peau on remarquait un pointillé hémorragique, quelques fois suivi par des suffusions sanguines noirâtres.

Les modifications créées dans la circulation par l'action de la chaleur, lesquelles nous avons ci-dessus rapporté, doivent créer nécessairement deux autres conditions,

FIG. 4.--APPARATUS FOR THE ESTIMATION OF THE AMOUNT OF GAS ELIMINATED FROM FOOD.

qui n'ont pas été encore démontrées par l'expérience, c'est-à-dire, la lenteur des phénomènes d'absorption et la diminution de l'activité des échanges dans les tissus.

Maintenant il sera facile à comprendre comme ces conditions secondaires peuvent concourir à aggraver certains états pathologiques dans les climats chauds; et pourquoi, dans ces climats, on ne doit compter beaucoup sur l'absorption rapide des médicaments.

## THE ANALYSIS OF THE GASTRIC JUICES FOR SOME DISEASES OF THE STOMACH.

By HUGH HAMILTON, M. Sc., M. D., of Harrisburg, Pa.

The accurate information gained by analysis of the contents of the stomach fluids in their normal condition, when the stomach is empty or in functional activity, is attractive to the physiologist because it places his work in a practical field; of benefit at once to the physician and his patient. One of the first indications of disorder of the stomach is the distension of the organ until the fermentive gases force their way through the cardiac orifice, sometimes carrying portions of the fluids or semidigested food with it. The flabbiness of the stomach walls themselves might be a cause of distension, but the ingestion of an abundance of easily fermented food only emphasizes the condition. The object of this thesis is to apply absolute methods to these phenomena, such as the exact volume of the organ, a way of determining the fermentive capacity of the food as a factor; the estimation of the HCl in its several combinations; the intermittent (functional) or continuous emission of stomach juices. The volume of the stomach measured by means of its capacity to contain a given amount of air at a pressure until it gives way has taxed the ingenuity of those interested. A recent simple apparatus is that of Dr. Kelling, of Dresden. (See Fig. 1.) In his investigations he elaborately entered into the details of the difference of water volume exceeding that of the air volume capacity of the stomach. In his cases the average was 72.3 per cent.

REMARKS.—7, 8, 9, 10, 11, and 12 are my own observations.

To estimate the fermentive conditions, a portion of the stomach contents is withdrawn after definite meals, in periods ranging from one to four hours, then the ingesta placed in a bottle and raised to the temperature of the person's body, kept there until fermentive action ceases, or for a given time, when the oven into which the bottle has been placed indicated the average proper body temperature of the particular individual. The bottle or flask is connected with the following shaped apparatus (Fig. 4), and the amount of gas eliminated from the food mixture read off at designated intervals. The abscissa of a scale may indicate time, while the ordinates will show the number of cubic centimeters of gases that may be caught over mercury

or water, depending in some cases upon the nature of the principal gases forming the volume of the effluvium (Fig. 5).

7 P. M., May 24, 1892, case (BR) of continuous secretion of the stomach juices.—The organ at rest contained about 1,300 c. c. After a mixed diet of meat, bread, and milk, 100 c. c. of this food was withdrawn, with the following results. Meal was taken between 6 and 7:

| At 7 hours—      | c. c. | At 7 hours—      | c. c. |

In these experiments it has been found that one drop hydrochloric acid added to 10 c. c. milk gave 9 c. c. of gas in 12 hours due to fermentive action.

| Hours. | Gas.                                                    |
|--------|---------------------------------------------------------|

| 3..... | 9, and with Congo paper showed 4.2 per cent acidity.    |
| 4..... | 5.75, and with Congo paper showed 8.6 per cent acidity. |
| 8..... | None in 3 to 4 or 12 hours afterwards.                  |

The remedies here are obviously salicylate and benzoate of soda, and in certain conditions small quantities of hydrochloric acid. The acidity of the stomach juices and its proper therapeusis is a fertile source of discussion. The mere fact of its presence by its effect upon certain “indicators” is at best of a qualitative index. The best methods of quantitative estimation are rapid volumetric ones, they give most conclusive results. We first find the total acidity by triturating 5 or 50 c. c. of the stomach contents with a  $\frac{1}{10}$  normal alkaline solution. With an indicator this will give you, for example, 0.182 “A.” The total acidity, if made up of the free and organically combined HCl would be exactly the same as the sum of these factors; but the amid-group acids qualify it at different times so that the factors vary considerably during digestion. This may be deferred until later.

The factors of investigation are—

- A. Total acidity.
- T. Total HCl.
- F. Fixed HCl (salines).
- C. Organic combinations of HCl.
- H. Free HCl.
- $a$  = value of amid-group acids.

Fifteen cubic centimeters of the filtered contents of the stomach are divided into three portions, the first of which ( $a$ ) is dampened with a clear, saturated solution of NaOCO<sub>2</sub> and dried with the other portions ( $b$ ) and ( $c$ ) over a water bath. Then ( $a$ ) is taken out, exposed one minute to a weak red heat, taking care that the sub-

FIG. 5.—PROGRESSIVE FERMENTATION OF FOOD.

The volume of gas in c. c. formed from the contents of the stomach taken at three periods, being subjected to a temperature of 38.8° C. from hour to hour upon 100 c. c. of the fluids.

stance is heated until totally colorless and white. After cooling, dissolve in distilled water and add a little clear  $\text{NO}_5$  to drive off the  $\text{CO}_2$ ; dry and neutralize with  $\text{CaO}$  or  $\text{NaOCO}_2$ ; then filter and wash the residue with boiling water, and triturate with  $\frac{1}{10}$  normal solution  $\text{AgONO}_5$ , indicating by  $\text{KOCrO}_3$ , known as "T" = total chlorides.

(b) This portion is dried an hour (*per se*) at  $100^\circ$  to  $110^\circ$ . When totally dry, the residue is wet with a clear saturated solution of  $\text{NaOCO}_2$ , and treated as in (a). This is considered the combined chlorides = organic and fixed chlorides "C" + "F."

(c) This portion is dried and burned; the  $\text{HCl}$  found in ash is considered fixed chlorides. "F."

Portion (a) is designated as total chlorides, A, (b) is designated as the mixed chlorides of organic substances and fixed chlorides; hence (a) — (b) = free  $\text{HCl}$  as difference known as "H;" and (c) is known as the fixed chlorides, i. e., salts, as "F;" then (b) — (c) = organic chlorides known as "C."

| Chlor-uric evolutive disturb.                                                             | Chloro-hydria or glandular re-active process.          | Qualitative changes in peptonization. |
|-------------------------------------------------------------------------------------------|--------------------------------------------------------|---------------------------------------|
| $\frac{\text{T.; F.};}{\text{T.}}$<br>$\frac{\text{F.}}$                                  | $\frac{\text{C.; H.};}{\text{C}}$<br>$\frac{\text{H}}$ | $\text{A.; a.};$                      |
| I. $\text{H} + \text{C}$ greater than normal = $\frac{\text{C}}{\text{H}}$ = Hyperpepsia. |                                                        |                                       |
| II. $\text{H} + \text{C}$ normal = $\frac{\text{C}}{\text{H}}$ = Normal.                  |                                                        |                                       |
| III. $\text{H} + \text{C}$ less than normal = $\frac{\text{C}}{\text{H}}$ = Hypopepsia.   |                                                        |                                       |

This is the best explained by the following tables:

| $\text{H} = \text{T} - (\text{F} + \text{C})$                                |                      |                                |                         |                                 |                    |               |
|------------------------------------------------------------------------------|----------------------|--------------------------------|-------------------------|---------------------------------|--------------------|---------------|
| $\text{a} = \frac{\text{A} - \text{H}}{\text{C}} = \text{I or less than I.}$ |                      |                                |                         |                                 |                    |               |
| Minutes.                                                                     | Total chlorides (T). | Fixed chlorides (salines) (F). | Free, $\text{HCl}$ (H). | Organic comb, $\text{HCl}$ (C). | Total acidity (A). | Value of (a). |
| 30                                                                           | 255                  | 182                            | 0                       | 73                              | 75                 | 102           |

To sum up the matter in the increased size of the organ, its capacity to endure strain shows the reasons for its dilatation are either a yielding of the walls or the continuous fermentive process. After defining these facts by absolute methods we have a means of relieving the disease with the action remedies, other things being equal, with comparative certainty from the information gained respecting anti-fermentives, as sodium salycilate or benzoate.

Respecting various painful dyspepsias it is important to fill the organ (it should not be overstrained), discover its weak and tender spot, and test the contents for acidity, A., which to a degree fixes the sort of soreness you have to deal with, whether benign or otherwise. The use of remedies such as pepsin or hydrochloric acids are matters that are exhibited with accuracy in the formulas shown respecting the different states of HCl in the contents of the stomach, as in the hyper, hypo, or a-pepsia states.

I trust that these few demonstrated clinical certainties may lead to a more sure method of treatment.

#### PRELIMINARY NOTE ON THE PHYSIOLOGICAL ACTION OF LANTHANUM, THORIUM, ITTRIUM, PRASEODYMIUM, NEODYMIUM, AND ZIRCONIUM.

By ISAAC OTT, M. D., of Easton, Pa.

The salts of these metals were procured from the Welsbach Incandescent Light Company, of Gloucester City, N. J. The nitrates were the combination used, and were soluble in water. The two bodies, neodymium and praseodymium, are two new elements separated from the old dedymium body by Dr. Van Welsbach in 1885. Their atomic weights were determined by Bunsen and Welsbach. The experiments were made upon frogs and rabbits.

The first element I shall take up is lanthanum, which was combined with ammonium to make it soluble in water. In the frog in one-half grain dose subcutaneously it increased the respirations and caused a feebleness of movement with a tetanic action, and finally all sensibility is lost whether the artery is ligated in one leg or not. Motor nerves when exposed are irritable; chest opened, and heart beating 34 per minute. In the rabbit, when a grain is gradually injected per jugular the pulse rate is hardly altered, but the arterial tension falls. The respirations continued after the heart stopped, while in another instance the heart was beating feebly five minutes after the respiration ceased.

#### THORIUM NITRATE.

A frog received at various intervals 20 grains subcutaneously. It caused increase of respiratory movement, then convulsive movements of the posterior extremities. There is a feeble response to strong irritation of the skin. The animal died in an hour and twelve minutes, heart beating 36 per minute. Sciatic irritable.

A small rabbit received one-half grain thorium nitrate per jugular. Respiration at first accelerated. In two minutes after spasmodic movements of the posterior extremities the breathing ceased, heart beating 100 per minute.

When a rabbit received an eighth of a grain at various intervals, it did not alter the pulse rate to any great extent, but depressed the blood pressure.

#### ITTRIUM NITRATE.

A frog received subcutaneously 12 grains of ittrium nitrate. In twenty-three minutes he sits in a stupid condition, with eyes closed, but jumps when his legs are irritated. Lies with mouth open; finally does not respond to irritation, heart beating 40 per minute. Has convulsive movement of legs. Sciatics irritable.

In the rabbit one-eighth of a grain per jugular lowered the pulse rate and pressure.

#### ZIRCONIUM NITRATE.

After injection of 38 grains of zirconium subcutaneously the frog crawls in a weak manner when irritated. Chest opened, heart beating feebly at 36 per minute; sciatics irritable.

In rabbit zircon did not perceptibly alter pulse rate, but depressed arterial tension.

#### PRASEODYMIUM.

A frog after he received 24 grains of praseodymium had increase of respiration and jumped about convulsively. When 12 grains more given subcutaneously he had convulsions, and at length responds very feebly to strong irritation. When 6 grains more were injected he died; chest opened, heart beating strongly 44 per minute; sciatics irritable.

In the rabbit  $\frac{1}{2}$  grain per jugular caused no marked alteration in pulse beat, but a depression of arterial tension. Praseodymium is stronger than neodymium.

#### NEODYMIUM.

In the frog 20 grains subcutaneously soon caused loss of movement; severe irritation produces convulsions and death; heart beating 34 per minute; sciatics irritable. In the rabbit 4 grains per jugular caused depression of pulse and arterial tension.

The following conclusions can be drawn from these experiments:

(1) That in cold-blooded animals they cause loss of motility and a loss of sensibility, which is in part cerebral.

(2) That they all depress arterial tension and not markedly alter the movement in warm-blooded animals.

(3) That in cold-blooded animals the heart continues to beat after death, but at a lower rate of speed.

(4) That praseodymium is a more toxic agent than neodymium.

## SECTION XI.—DISEASES OF CHILDREN.

## ADDRESS OF THE PRESIDENT OF THE SECTION.

### WHOOPING COUGH AS SEEN IN THE ROCKY MOUNTAINS.

By J. M. KEATING,\* M. D., LL. D., of Colorado Springs, Colo.

*President American Pediatric Society; President Section of Diseases of Children, Pan-American Medical Congress; Fellow of the American and British Gynecological Associations, Etc.*

The honor which was conferred upon me by the request to organize this section carried with it a responsibility which I fully realized, and, under other circumstances, I would have hesitated in accepting the trust, living, as I do at present, in a section so far removed from those who would be my active coöperators. But, with the aid of one so efficient, so energetic as our secretary-general, Dr. Reed, and with the active assistance of our secretary, Dr. Crandall, I felt that our meeting was bound to be a successful one, and I was proud to be its standard bearer and to give all the aid of my enthusiasm in the good cause. What more attractive study is

\* Since deceased.

there than that of pediatrics? What more interesting theme than that which relates to the growth and development of the healthy babe, who will in future bear upon his shoulders the responsibilities of the world—those that relate to family and to government? What more satisfactory study than that of disease at an age when all natural processes are in our favor? The very subjects of which we write are those that are nearest and dearest to us in our individual homes, for they touch our love as well as our sympathy. They teach us how to defend those little ones from the aggressive influences of diseases which luxury and avariciousness have brought into our midst. They teach us the cause and, by knowing it, we learn its cure. The object of this congress has been to bring together all the workers in the vast field of medicine in this great hemisphere, and we hope by the happy association of scientific meeting and social gathering to learn more of the effects of climate on disease, both in its causative and curative relations; to study also the effects of individual resistance through racial peculiarities probably due to climatic influences—a subject which is looming up as one of vast importance.

I desire to call your attention to the subject which I have chosen for a few remarks to-day, hoping that it will bring forth some discussion and that the investigation which I have undertaken may prompt others to follow out this same line of thought in connection with other diseases of children in the various sections of this great country. Since living in Colorado, after having had quite an extensive practice on the Atlantic Coast, I have been very much struck with the differences in various affections of childhood with which I had been previously very familiar. These differences certainly were not due to peculiar conditions of the individual, which might be said of those who are phthisical and who had congregated in large numbers at certain favorable places and where certain common symptoms might depend upon the disease and not the climate; but in children who, as a rule, are healthy subjects, peculiar manifestations of disease undoubtedly depend upon local influences, which may be either those of soil or those of climate. For this purpose, I addressed myself to a number of prominent physicians of Colorado and New Mexico, and have collected considerable data, from which I take the material for the paper that I present you to-day. It is not necessary for me to dwell at any length upon the subject of whooping cough. You will find all that I have to say upon this subject in the article in Pepper's System of Medicine and in a recent publication, Mother and Child. I may say that I believe the disease to be microbic in character and capable of being influenced by treatment that will reduce the attending laryngeal and tracheal catarrh and act as sedative upon the nervous system. We have all noticed that children do best with whooping cough who live in the open air and, for that reason, it is always recommended, when possible, to send our cases to the country or to the seashore, to dress them in flannels so as to prevent the catching of cold, to let them lead lives which are invigorating and which will tend to fortify their digestive processes; in other words, that with fresh air and tonic influences the disease will run a mild course and terminate in recovery.

The great question which has often attracted attention is whether the violent paroxysms which one so often sees attending this disease, and which result in hæmorrhages, at times most alarming, are productive of organic changes in the heart and lungs which will seriously impair them as to growth and development. It must be said that at times we do meet with cases of this character, and possibly for years these little ones will be affected with evidences of cardiac strain or emphysema that will require the most careful attention to overcome so as to bring them to the standard of a healthy adult. But if that is so for those who live upon the sea level, how is it for those who live upon the vast slopes of the Rocky Mountains over one mile high? It is not necessary for me to go into the dynamics of altitude. The writings of Denison and Solly in this country, and Theodore Williams in England, have proved conclusively that the attenuated atmosphere, or, in other words, the relief from atmospheric pressure, has a marked influence in increasing the necessity for pulmonary activity and influencing the heart to a very great extent. The respira-

tions are either increased in rapidity or rendered deeper and the pulse rate is quickened until an equilibrium is maintained. The necessity for a larger supply of air naturally lays a greater strain upon the heart and lungs upon exertion, and one would imagine that where any interference would take place through spasms of the glottis the force of the expiratory effort would be intensified under the conditions named. We find also in studying disease in the adult in high and dry localities that the bracing winds and remarkable electrical phenomena of the atmosphere produce a nervous condition which seems to intensify those affections which have in them more or less of a marked nervous element.

Of course one finds that the so-called nervous temperament which is associated with anæmia is benefited by an out-door life, which gives appetite and helps to increase the blood, both in its amount and richness, and such cases seem to do well. But the essentially neurotic type of individual—and I am speaking more especially for the women, as they form the larger part of my practice—are apt to suffer from insomnia, irritability, and all such evidences of excitement. I have also noticed in a few cases that children are more or less subjected to the same influences, and certainly with them we must be able to study more satisfactorily the effects of climate, because they are less influenced by what they hear and by dissatisfaction with their surroundings. I have had two most interesting cases of spasmodic asthma—one in a child born here, who is ten years old, but who developed the disease in early childhood, and who became more and more affected as she grew older. She was highly excitable, intelligent beyond her years, and of an essentially neurotic type. The parents were both perfectly healthy. Exposure to the wind when driving would bring on the most severe attack of asthma I ever saw in any individual, which would last for several days. She would become highly cyanotic, the pulse would become extremely irregular and intermittent, the respiration very frequent and very shallow, and, indeed, on two or three occasions I felt that it would be impossible for her to survive the attack. Upon removal to the Atlantic Coast the child has remained perfectly well for now a year. One would then naturally suppose that in this section of country the spasmodic element of pertussis would be much increased; in other words, that the nervous system would be rendered more susceptible to the influences of the disease.

One of the most interesting descriptions—and from my long residence in the locality I can vouch for its accuracy—is the paper on “High altitudes and their climates” by Theodore Williams, read before the Royal Meteorological Society of London January 18, 1893. In the description of the climate of Colorado taken from this paper we find that in regard to rainfall it varies from 8.71 to 22.30 inches; at Denver, 14.17; Colorado Springs, 15.17; Santa Fé (the capital of New Mexico), 14.17 inches; at Gunnison, which is 7,680 feet, 10.02, and at Leadville, 10,200 feet, only 12.80 inches. Throughout Colorado scarcely any rain falls from October until May, and during the months of July and August most of the precipitation occurs, at which times thunderstorms are of frequent occurrence. Snow, which occasionally falls in the autumn and winter, rarely does so to the depth of more than a few inches, and only in the mountains does it remain for any length of time. The relative humidity, of course, varies with the season of the year. For two-thirds of the year it is remarkably low; for the other third, when the rain storms are frequent, the average is brought up so as to bring a percentage varying from 46 to 58. As the number of days in the year in which rain falls is calculated to be about 85, and on most of these there is simply a thunderstorm and the rest of the day perfectly fine, the amount of sunshine is simply remarkable, and permits one to remain out of doors practically most of the year. One of the results of this out-of-door life is the remarkable resistance to attacks of bronchitis, which seem so prevalent in the East, as the result of exposure to sudden changes. Children rarely take cold, and yet the changes are remarkably sudden. At sundown in winter the mercury may fall within an hour or so 30°, 40°, or 50°; but probably the excessive dryness of the atmosphere is in itself the cause of the immunity to the acute catarrhs, both laryngeal

and bronchial, so prevalent in a moister and lower place. In order to find out what influences, if any, these atmospheric peculiarities and also altitudes had upon a disease like whooping cough, I have collected and present to you the experience of a number of physicians, who have kindly replied to my circular letter. These I give, as follows:

| Name.                  | Place.                   | Altitude.    | Experience.                                                                                                                                                                                                                                                                                                                                  |

| T. H. MacNaught.....   | Denver, Colo.....        | 5,000        | Whooping cough cases are mild, with few complications or sequelæ.                                                                                                                                                                                                                                                                            |
| L. M. Griffin.....     | Boulder, Colo.....       | 5,200        | Whooping cough I find more fatal, through complications and neglect upon the part of parents, than one ought to expect. Pneumonia, progressive; emaciation and cerebral congestions.                                                                                                                                                         |
| E. Stuver.....         | Rawlins, Wyo.....        | 6,307        | We only had one epidemic last winter; disease severe; quite a number of young children died.                                                                                                                                                                                                                                                 |
| A. T. King.....        | Pueblo, Colo.....        | 4,600        | Whooping cough less severe; complications about average; sequelæ less grave.                                                                                                                                                                                                                                                                 |
| Frank Tinny.....       | La Junta, Colo.....      | 4,060        | More severe than in eastern Kansas.                                                                                                                                                                                                                                                                                                          |
| James Wroth.....       | Albuquerque, N. Mex...   | 4,950        | Whooping cough much milder; only fatal case a child two weeks old, disease appearing first week of life.                                                                                                                                                                                                                                     |
| P. D. Wrathwell.....   | Denver, Colo.....        | 5,000        | Our fatal cases complicated with pneumonia.                                                                                                                                                                                                                                                                                                  |
| N. Wiest.....          | .....do.....             | 5,000        | Have had great many cases in private and hospital practice in Denver; find the disease milder by far, but very persistent. No important complications or sequelæ.                                                                                                                                                                            |
| N. W. Bellrose.....    | Eaton, Colo.....         | 4,822        | Only one case—boy of 4; good recovery.                                                                                                                                                                                                                                                                                                       |
| John Gaw.....          | Leadville, Colo.....     | 10,000       | Generally mild, without complications or sequelæ.                                                                                                                                                                                                                                                                                            |
| Francis H. Atkins..... | Las Vegas, N. Mex].....  | 6,450        | No variation from standard of sea-level types has been observed; no sequelæ. Have lived 20 years in the great plains, 13 in New Mexico, and 8 in Las Vegas.                                                                                                                                                                                  |
| H. B. Moore.....       | Colorado Springs, Colo.. | 6,000        | Nothing peculiar in its clinical course.                                                                                                                                                                                                                                                                                                     |
| F. H. Lay.....         | Denver, Colo.....        | 5,000        | Mild complications and sequelæ rare.                                                                                                                                                                                                                                                                                                         |
| J. N. Hall.....        | Sterling, Colo.....      | 3,900        | Saw an extensive epidemic in Sterling, with no death or serious complications.                                                                                                                                                                                                                                                               |
| N. D. Estes.....       | Alamosa, Colo.....       | 7,584        | Whooping cough has been mild, unattended with complications; no deaths.                                                                                                                                                                                                                                                                      |
| Jesse Hall.....        | Greeley, Colo.....       | 4,750        | Very mild; few cases; no sequelæ.                                                                                                                                                                                                                                                                                                            |
| F. Bancroft.....       | Denver, Colo.....        | 5,000        | Whooping cough (last epidemic) very severe one; 8 to 10 years age quite severe.                                                                                                                                                                                                                                                              |
| J. H. Finfrock.....    | Laramie, Wyo.....        | 7,400        | "Nine months winter and three late in fall." Whooping cough common and mild; never knew of a death; often prolonged; complicated, with bronchitis.                                                                                                                                                                                           |
| Charles Denison.....   | Denver, Colo.....        | 5,000        | Worse in some cases because of mechanical effect of rarified air favoring emphysema.                                                                                                                                                                                                                                                         |
| James A. Hart.....     | Colorado Springs, Colo.. | 6,000        | Have practiced twenty years in this locality, and found the disease about as represented in the text-books. Some epidemics severe and some mild.                                                                                                                                                                                             |

We have thus endeavored to ascertain the views of those who are pretty well scattered throughout this section at various altitudes, and though it is absolutely impossible to give a positive reply to the questions asked without a record being kept of cases, as should be done if scientific work is to come from our daily experience in the future, every man is impressed more or less with the character of the cases which have come to his notice, and these statements which I have just quoted possibly represent the facts as they really exist. We may then conclude that there is very little difference in whooping cough as seen in this section from what we have been accustomed to note on the Eastern coast, and that the little difference is possibly dependent upon epidemic influences. The most serious complication certainly seems to be pneumonia, and though this is a complication which is to be feared everywhere, it has the greatest significance in an altitude where pneumonia as a rule is a very fatal disease. In New Mexico, according to Dr. Francis H. Atkins, who is a well-known writer on the climatology of that section, sequelæ are rare. Dr. James Wroth, of Albuquerque, whose experience is most reliable, also dwells upon the extremely mild character of the disease. Dr. John Symington, of Santa Fé, whose practice has been an extensive one for many years, speaks of the disease as being mild and rarely complicated, and this at an altitude of over 7,000 feet. But that mildness of climate has very little to do with this result is shown in the statement of Dr. J. H. Finfrock, of Laramie, Wyo., at an altitude of 7,400 feet, who quotes Bill Nye's description of their climate as "Nine months winter and three late in the fall," in which he notes that whooping cough is common and mild, but that it is frequently complicated with bronchitis, which could be expected in so rigorous a climate.

In summing up we may therefore conclude that as the cases of whooping cough receive their greatest benefit from living in the fresh air on the sea-level, so possibly it is the amount of fresh air and outdoor life which mitigates its severity on these mountain slopes; that in children who are healthy altitude of itself does not seem to influence to any very great degree the strain of the cough in the production of heart trouble or seriously impair the lung structure; that the robustness and resiliency of youth soon combine to maintain the balance of the circulation, and that also the nervous system of the child, though more impressionable to reflex irritations, does not seem to be so susceptible to climatic influences as that of the adult.

### THE INSANE DISORDERS OF CHILDHOOD.

By JOHN MADISON TAYLOR, A. M., M. D.,

*Professor of Diseases of Children, Philadelphia Polyclinic; Professor of Diseases of Children, Medico-Chirurgical College; Assistant Physician to the Children's Hospital, Assistant Physician to the Orthopedic Hospital, Neurologist to the Howard Hospital, Fellow of the College of Physicians, Secretary of the Philadelphia Neurological Society, etc.*

It comes in the way of those who see much of children's diseases to meet with many cases of what I prefer to call insane disorders. A consideration of these, rather in the line of their nature and requirements than elaborate speculation as to causation and phenomena, may prove of use to the practical physician.

Insanity arising from the same sources whence it comes in the adult is rare in childhood, but mental defects are only too common, and grow worse with startling rapidity unless most wisely handled. Minor mental deflections or shortcomings which may escape attention form the fertile ground for ineradicably evil mental attitudes to take ready root. Active disease frequently disturbs the cerebral functions,

and these may not recover with the subsidence of the acute process, even though the structural damage be small. When this occurs, it is important carefully to direct even the simplest educational and disciplinary measures in order to inhibit further lapses and regain healthy tone. In a long experience in dispensary work among children such cases have occupied much of my attention and certain principles of guidance have become formulated in my mind, which may be trite enough, but nevertheless prove of service to others.

My purpose is to call attention to the casual factors which should be scrutinized by the physician so soon as the least ground for apprehension arises, and after a general consideration of these point out how to deal with suspicious phenomena. The causes of these states are many and of wide reach. Some are the outcome of depressed physical powers due to want and misery; many more, however, are the result of careless usages, complications, and vice. In certain parental tendencies there lies danger. Vitiating appetites, as for alcohol, opium, or even tobacco, interlace with other, or are themselves a ground for, diseases of body as well as of mind. Tuberculous families frequently present instances of acute nervous diseases, terminating in swift fatalities, and offer also little resisting power against exciting causes. Then there are families of notably unstable nervous equilibrium in whom acute diseases or overwrought emotions work sad havoc. Cultivation of the emotions in the way of mundane or heavenly things, or, per contra, an undue asceticism or self-repression, may exercise a hurtful effect upon the offspring. When these various causes thus sketched out, and of limitless scope and variety they are, become super-added, one to the other, by the marriage of a tuberculous father to an hysterical mother, or an alcoholic father to an overconscientious, highly spiritual mother, disaster may be predicted for the issue. Again, upon the impressionable nature of developing nervous tissues of a child hypersensitive by heredity, exciting causes act only too overwhelmingly. Influences capable themselves of disturbing even a healthy-minded child are many. Acute febrile diseases produce commonly delirium, which is itself a transient insanity, and this may pass utterly and quickly away, or leave an indelible stain on the cerebrum. That surprising condition which we regard as accidental, because as yet we do not know how to explain its origin, known as precocity, is a source of peril if not an evidence of mental unsoundness. It is almost never a ground for parental gratulation, and only rarely fulfills youthful promise and not seldom predestines its possessor to neurosis.

The childish brain is very vulnerable at all times, and demands for its best development slow and undisturbed opportunities and wholesome conditions. Very much mental stimulus is always hurtful, although pure intellectual pushing is said by Charcot to be in itself incapable of harm, provided other wholesome physical and moral conditions are maintained. The emotions evidence themselves first in mere animal delightedness, even then running along the lines of ancestral traits. Here the parental coloring of mind, habit, or exterior is shown in curious faithfulness of detail. Even at this stage bad habits may become sketched in upon the impressionable receptive centers, which, either encouraged or neglected, form the ground for future calamitous happenings. The exciting cause of mental disturbances differ in some respects from those of the adult. One of the most serious is rapid alternations of temperature. Children notably bear heat and cold less well than grown folk, and a baby laid with its head defencelessly toward a hot stove has in several instances been driven into acute mania. Children bear pain unusually well so far as mental distress goes. Much attention has been drawn of late by rhinologists to adenoid growths of the naso-pharynx as a cause of mental degeneration. Disorders of the digestive organs may form fundamental perversions which result in a series of reflex irritations, setting up, usually, only transient disturbances of mind. The cause being removed, recovery ensues. Intestinal parasites cause a variety of nervous troubles, but very rarely actual insanity. Hurtfully directed moral causes are very efficient factors in disturbing the mind, both temporarily and more seriously. The shock of fright or overwhelming dread is powerful for harm even in

children perfectly healthy. Religious teachings of a lurid hyperbolic type act as a lever by which great harm is wrought. As a potent accessory factor superstition has in all times been an agent to dethrone unstable minds. Acute disease is a fertile source of harm; a scarlet fever, or typhoid, especially if accompanied by hyperpyrexia, very often reduces a perfectly healthy, vigorous child to an imbecile or a maniac. Masturbation was credited with overmuch power for mental harm, but is certainly responsible for some. A brutal, drunken father, aside from prenatal conditions, causes terror and woe to young children, as well as perverted morals. Example is almost as powerful for harm as ancestral traits.

Children subjected to long periods of want and exposure are certain to fail of right development and to bear some stain in the moral senses if not in mental acuity. Hence, the waifs and strays gathered up by the municipality or by philanthropic societies are of questionable mentality and demand unusual care in implanting the seeds of morality and right conduct. These must receive a more primitive form of instruction than others who have enjoyed a better start in life. The fundamental concepts being at fault, too advanced instruction only confuses.

To come at a statistical knowledge of the prevalence of mental disorders in children will always be hedged about with grave difficulties. Parents are not usually watchful as to these states, and are even more rarely competent observers to interpret mental deflections and shortcomings. Moreover, if a suspicion arises in a mother's breast as to the mental soundness of her offspring, it is likely to be tight locked therein and shared with no one living, until the conviction is reluctantly forced upon her consciousness from repeated overt acts. Moreover, it is rare to meet a mother capable of rightly training a child not altogether wise. Some, happily, are admirably gifted in this respect, and if the mother is capable of being or will submit herself to be carefully instructed how such a case shall be managed sometimes the very best results come from home care. It has been my experience to see some excellent instances of these mothers, and I am inclined to believe that this particular possibility may be very much amplified. Again, I have found immediate relatives who both could and would undertake this care, and bring about excellent results. As a rule, the mother is so hampered by her emotional view that her judgment is not good in respect to her own child. Then, the problem arises to whom it may be committed. It has been my custom, and I think from it some excellent results have come, to always search about among the home possibilities of such a case, and not seldom there has been found some good maiden woman, or widowed aunt, or childless person, who could be taught to do what the same child's own mother might be able to do for some other woman's child. We have before us always the admirable example of the insane colonies of Europe, where such excellent results come from treatment in private houses, and whenever this can be accomplished it is better so to do. The well-regulated asylum is abundant for good, and of the excellent specially instructed folk who rule therein I have little to say but of praise.

My theme here is the conduct rather of those who may not enjoy these advantages, either because they are not adjudged fit subjects or whose people decline to send them there. Moreover, the great body of mental suspects who escape statistical record is at the mercy of the family doctor, and upon him lies the responsibility of directing their care and teaching. Hence the bulk of these are to be treated at home and the average medical man enjoys a grave privilege.

In questioning, examining, and otherwise dealing with the child as a neurotic patient, success in arriving at right conclusions depends as much on the demeanor and conduct of the physician as on his knowledge. With the adult this may possibly not be true, but in respect to the less differentiated mental organization my proposition will hold. Skill born of much experience is needed to win the confidence of a child, and to this must be added tact and gentleness. Here again, gentleness should not lack a strong infusion of firmness and decision. If the patient be one whose mind or disposition is disordered it is of double importance to approach the

problem aright, either to learn essential facts or to apply remedies. Medicines will often be quite needless, but moral control and tactful domination must be ever forthcoming. The physician should succeed in impressing his personality upon the patient. He must represent embodied power, helpfulness, and justice. In some instances he may be of loving manner, pleading with the obstinate but sensitive nature. More often he needs to pose as a kindly yet overmastering being, to whom confession must be made soon or late. Again, over voluble, highly graphic confessions must be discounted too. Always obedience must be exacted, but tempered by due consideration of immediate necessities, and no more. Gradually simple yet systematic measures may be given shape and pushed steadily to an end. Much tactful shifting of unessential measures are at times demanded, patience and firmness always.

The insane disorders, as the term is used here, is meant to include not only insanity, but that mixture of insanity and hysteria which is oftentimes indistinguishably blended. Nor must hysteria in the larger significance of the word be excluded. Hysteria in imitating as it does all neuroses yet never presents a picture faithful in essential details. It offers the more superficial appearances, but is wanting in the testamentary clinical findings. The faults have especially to do with the phenomena of onset; also with the basal symptoms such as evidence structural change and with the true course of the disorder imitated. Hysteria, while preëminently an imitation, is not all, nor nearly all, true simulation. In children it is rarely suspected, but always possible so soon as the receptive faculties and power to form concepts are fairly established. The heedless examiner will often give to the shrewd observation of the hysterical or insane child leading points on which to fashion its symptom groups by his idle words and leakage of thoughts while thinking aloud, and may be thus misled afar. Moreover, the distinction between these closely resembling conditions is oftentimes a purely relative matter,\* to be decided partly by the personal factor of the observer or the social or individual standard of the patient. Again, hysteria and organic brain disease may coëxist, not often in the child, 'tis true, but will there prove most puzzling.

Moral perversions are hard to distinguish from merely evil and vicious tendencies which are acquired by a stupid, impressionable subject. The moral imbecile is inherently bad. He is an instinctive liar and thief, cunning and skillful in mischief-making, and if in other ways seemingly competent, yet unspeakably provoking to the parent or teacher. To know how to best deal with such is generally conditional upon a clear decision as to whether one has to do with an ineradicable vice or disease, here probably synonymous, or a possibly removable disorder. The main thing is not to attempt too elaborate a plan of improvement, and when he be under favorable surroundings to exercise infinite patience and use abundant time. He is to be made to know that while not to be trusted or believed the utmost encouragement will be enjoyed so soon as evidences of improvement are shown.

Along with obviously wicked acts coëxist often evidences of disease process as convulsions. It is often most difficult to determine if these be epileptic or hysterical. These may be in combination, too; hysterical attacks in an epileptic subject is a blending to which there is no key. Typical clear-cut cases of neurotic maladies are none too common, and ordinarily it is only by the after fruits of treatment that they shall be determined. A large familiarity with hysterical states increases ones respect for the difficulties of differentiation. Charcot's diagnostic powers of hemianæsthesia, affections of sight, hysterogenic zones, the effect of æsthesiogenic agents upon sensibility and motility, many times can not be readily or promptly applied. Then collateral evidence must guide the physician. Hysteria must have some sort of audience always, and wherever vanity can be detected, or gravely suspected, it will help to determine the nature of attack. The instinct of the physician is also a help, but must not be masked by prejudice.

In the management and moral training of children of hysterical or maniacal tendencies the first step to be gained by physician or care taker is to win their

confidence. The best method to pursue is to show and preserve a frank, quiet, yet persistently friendly, demeanor. In first interviews it is wise with all children to avoid a too direct and impulsive approach. Childish concepts come slowly; conclusions which are being formed with no great promptitude should not be hurried. Overprecipitancy offends, and the result is negative. Very much the same courteous, straightforward methods win a child which prevail with the elder. I have elsewhere emphasized this (*I, Univ. Med. Mag., Aug., 1891*), and am more than confirmed in my views. It is well to efface as nearly as possible the differences of age or position between the patient and physician. Assume both to be on the same plane, the one simply taking the initiative. It is inscrutable to me how those who talk baby talk, as it is ludicrously miscalled, to children, ever succeed in rendering themselves otherwise than most offensive. There is nothing winning to the feeble intelligence in being treated as an animal. So, thrusting of thumbs in the unprotected abdomen, chucking under the chin, etc., may convulse the infant with reflex laughter or at the grotesque figure of fun cut by the one so acting, but does not inspire confidence or admiration. It is like well-meaning folk who attempt to converse with a foreigner by using broken English. This is no light matter here discussed. Knowledge of the mental processes of the patient one must have, and accurate information only comes through intelligent questioning. I have repeatedly been able to secure the attention and frank answers of a child which my assistants had utterly failed to get, by conveying the impression that I was just such a person as themselves, who asked straightforward questions and fully intended to obtain equally candid replies. And if this be true of the medical man, in rare interviews, how much more needful is it that those who watch and direct the daily progress of the child shall proceed in the same frank, honest fashion ever. Punishment is sometimes needed; sharp corporal punishment, too. Some children of low tone or vicious hysteroidal character are amenable to no other argument. Who shall administer this and when is of the gravest importance, and only harm comes of lack of judgment here. More often gentle domination or kindly encouragement will suffice. A jocose, bantering tone also offends. Begin by questioning the attendant, parent, or nurse, thus allowing the child to take bearings and see you are not an ogre; then proceed to gently draw out the childish thoughts by speaking of perfectly comprehensible subjects first and others indirectly, and finally directly question.

It is often most difficult to convince people who assume the care of poor children, and who are themselves simply well-meaning philanthropists uninstructed in matters of mental development, that the morally or mentally infirm should not be allowed the same measure of privilege and responsibility permitted to others. This overconfidence many times leads to disaster for which the society may be held to account. The members of such societies should inform themselves carefully not only upon the subject of the varying capacities of the individuals entrusted to their charge, but in a general way the proper means of managing those whose mentality is either essentially below par or undeveloped through vicious suppression and perversion. It has been my privilege to be connected with such in an advisory capacity, and it grieved my heart frequently to see glaring mistakes made partly through well-intentioned ignorance and not seldom from vain self-sufficiency.

I could relate instances of moral imbeciles shrewdly manipulating the good ladies for their own selfish ends and becoming irretrievably ruined themselves, for nothing so permanently destroys all remnant of moral sense as the exercise of thieving and lying propensities upon credulous philanthropists. But if this is bad for boys, how much worse to allow girls to grow up through the critical periods of puberty unguided in the essentials of self-respect and purity, and become exposed by their deficiencies in moral restraint to the many temptations offered by too great liberty of speech and action. Several lamentable instances of sexual perversion and social destruction have come my way even after I had clearly pointed out the danger. The component members of these societies too often forget that human children vary

widely, not only in mental capacities, but in degrees of moral stain from ancestry and training. It is too often assumed that, given reasonable opportunities, all children will tend steadily to improve. The children of pauper and criminal classes need most careful watching and unusual training in the fundamental principles of morality. Instead of this they usually get too much liberty and far too much religious teaching. The training in religious thoughts and observances has a tendency to foster an exaggerated emotion, which is in some ways closely allied to sexual excitement. Let the moral instruction always precede the religious. Appended are the notes of three cases—two of no great interest, but one rather unique. Several such of the deepest interest have come under my observation, but I am not permitted to use them freely. One I give in illustration of a vicious tendency, but large general intelligence. A girl born of vigorous parents, but on the mother's side frequently recurring valvular heart disease. The child had a congenital aortic insufficiency so grave as to create astonishment in the minds of physicians who examined her to believe that life should continue. Here was a very great amount of physical and mental activity constantly maintained and unchecked by the parents. Death occurred at about 9 years. This was an instance of great precocity—especially voluble and shrewd in recognizing with unerring certainty the foibles and weaknesses of whomsoever she came in contact, managing those about her with a tact and adroitness to which too high admiration could not be conceded. Large judgment was here exhibited in manipulating others, but her purposes were often unclear. Long before it would have seemed possible for the small creature to learn bad language, for the father was peculiarly free of such habits, the skill and vigor of her profanity would have put a Texas cowboy to the blush. The calm effrontery of her lies were only equaled by the adroitness which was exhibited in covering up her discovered errors and mischievous failures. I have amused myself and indeed gathered much instruction in listening to her caustic critical remarks, when about 5 or 6 years old, on the personal characteristics of those whom she knew. Moreover, she never erred a second time, if once the error was committed, of exceeding her privileges overmuch, especially when swift punishment ensued, but would persistently drive a timid or undecided person, as her own grandmother, to the verge of distraction by a well-planned system of petty annoyance, skillfully pursued.

I could relate many instances of all these and other vagaries, but need not. The child was morally insane, but of such rare wit and intelligence, showing such tact and wisdom at times, as to convey the impression of her being (in sharp antithesis to case I) possessed of the arch fiend, whereas case I might be deemed of angelic descent. Here was an extremely bright, intelligent child—selfish, cunning, untruthful, cruel, and profane—a perfect picture of an almost hopeless mental invalid.

Should such children as this receive the thorough systematic training upon the lines laid down by Fröebel, involving a gradual awakening of the dormant faculties, I am confident great gain might be hoped for. It is my desire yet to see this kindergarten system thoroughly and persistently tried by fully competent teachers on unpromising cases. The limitations as sketched out herein must form a serious barrier to satisfactory results in most instances.

Another case to which I may only briefly allude: One in whom since babyhood a second personality or companion constantly accompanied the child, to whom all matters of doubt were referred. If asked a question this being is consulted by a side speech and the answer then given, or perhaps a difference of view arises and disputes ensue. Again, sometimes the child comes to parents or others and announces that "I have been to see B., and he and I talked over this or that," and arrived at certain conclusions which served as an imperative rule of guidance. There are other evidences of a very exuberant imagination, of a possibly hysterical nature, but no distinct signs of insanity except the delusion out of which the child can not be reasoned. My opinion is that as time advances and educational measures are pursued this will pass away.

*Case I.*—Helen Foulke, aged 9 years; first child of healthy parents; family history good for physical vigor; on the mother's side a great deal of neurosis with a distinctly religious coloring, coming of a race of Quaker preachers; one uncle, a man of large general intelligence, regarding himself as definitely under divine guidance, even in the matter of catching trains, for which he refuses to consult time-tables, etc., acting perpetually upon this heaven-sent impulse, yet falling into very few catastrophies. H. F. healthy as a baby in all respects. At 18 months had whooping cough, during which asthma developed, and, while very restless always, is very bright and intelligent, but even at that early age showed a marked ability to amuse herself, rather resenting outside interference. At 3 years of age had a sharp attack of pneumonia, which was probably, from the description, bronchitis with asthma; evidently extremely ill; for a time lay unconscious; some cerebral excitement even then, starting up suddenly and crying out loud for no known cause. During this winter there were three attacks similar to this. On recovery, began to have imaginary playmates, whose names were "Dewey" and "Gee." These were distinct personalities, apparently sexless, with whom she had long systematic conversations, arranged the disposition of her day, and these shared with her in all pleasures, which were largely solitary. Occasionally other imaginary people were introduced into this coterie, of different names. These frequently assumed the individuality of various pieces of furniture, which acted as a sort of negative background for the more active characters, "Dewey" and "Gee." As time wore on these inanimate objects were given human names and regarded as regular companions, with whom long hours of perfectly cheerful play were passed. Her family assumed this to be merely the play of a rather exuberant imagination, because the child could be readily diverted from these to ordinary practical affairs. She was otherwise entirely cheerful; indeed, rather of overexcitable spirits, and in most matters quite rational. The two regular companions and herself held long conversations, and when other children would come in to play with her, the two imaginary ones were brought into the conversation as much as possible; at least, to the extent to which the other children were capable of comprehending. Child playmates were comparatively rare in the isolated home, and therefore this imaginary couple were regarded rather as a boon than otherwise by the parents. The curious fact was observed by neighbors and visitors that Helen would almost never take hold of any object, even those which she had endowed with names and individualities, and with whom she conversed most freely. At 4 years of age she went to a kindergarten, and while there it was almost impossible to make her enter into the regular methods of the school, but on coming home, she would go through the entire performance with the utmost accuracy, showing there was no lack of comprehension. Also, the child failed to recognize orders of the teacher for a long time, simply ignoring them, but gradually got in the habit of submission. At 7 years of age she went to a regular day school and gradually got adjusted to regular discipline. She finally became interested in school work and distinctly overwrought herself, occasionally falling into hysterical conditions. About this time, also (between 7 and 8 years) she had an attack of influenza, which recurred three or four times, accompanied by a good deal of psychical disturbance, and after this fell back into a condition of physical apathy. There no longer appeared the active excitement, the voluble conversations, and such like, but she dreamed dreams both sleeping and waking, the results of which were related, not very frankly, to her mother. For some time she exhibited great slowness in everything, physical and mental, though all this while a moderate degree of intelligence was maintained in practical matters. She gradually grew more talkative and argumentative, discussing most exhaustively the pros and cons of the smallest matter. Gradually religious ideas became prominent; she became sleepless, lost appetite, etc. Then a period of three weeks intervened of very great excitement, coupled with terror. The house was peopled with wild animals, of definite kind and of aggressive fierceness, which kept her in a state of perpetual consternation. She frankly admitted to her mother about this period that she knew she was crazy, declared herself to be the victim of imagination, or worse, and would endow the pictures of living objects on the wall with malignant tendencies, and beg her mother to turn them face down. At 8½ years of age she suffered an attack, rather prolonged, of fever with meningeal symptoms—pain in the back of the neck, constipation, and finally, troublesome diarrhea. At one time a collapse occurred for twenty-four hours, when she was thought to be almost dead. During convalescence there occurred a period of intense excitement for ten days, with active imaginings, and then suddenly intervened the former state of apathy. A period of complete mental deafness occurred for about five months.

This girl came under my observation in June, 1892. There had then occurred an attack of chorea, which in all ordinary respects seemed true chorea. The child seemed rather stupid, filled with sudden fears and certain definite weaknesses which prevented her from walking straight, and also hallucinations of fanciful nature. I found a good deal of irritation about the nasal passages which it seemed necessary

to cure, and, not to prolong the account overmuch, in two or three weeks this was accomplished very nearly. There were no adenoid growths of the pharynx. I directed that she should spend the summer at the seashore, where she improved greatly, the asthmatic attacks disappearing, and the slight naso-pharyngeal catarrh subsiding almost entirely. The mental condition improved very much.

In the autumn, her physical condition being enormously better, and her general intelligence, too, giving great hope of thorough repair, there then intervened a period of extraordinary religious exaltation of a very picturesque kind, and just such as I imagine would convince people of strong religious convictions that this child had been breathed upon directly by the Spirit of God. She had been under the immediate influence of an overreligious servant, who had played upon the impressionable nature of the little girl, had taught her all manner of religious phrases, and done just as much mischief as she could possibly contrive. Thereupon, her pupil proving extremely apt, there transpired a large series of interesting religious phases: One while she would eloquently expound her view of passages of Scripture, her views upon the condition and appearance of heaven, what people should do to enable them to secure residence in the abodes of bliss, etc. There were vouchsafed to her glimpses of heaven, which she described most graphically and charmingly. There finally grew in her the overmastering desire to die and be a blessed angel. As to what she should do and where she should live, how conduct herself, etc., no devotee of the Middle Ages brought up in a nunnery could have more vividly portrayed; indeed, she exhibited a grasp of knowledge of the details of ordinary religious teaching which was out of all proportion to what her previous training would have warranted, giving any casual observer the impression that much of this was actual revelation. Her mother says that this was a feature frequently repeated in various members of her own family, who would fall into ecstatic states, during which astounding revelations were made to them. What might have transpired had not these good people been bound down by the conventionalities of the Society of Friends it is impossible to estimate.

In October, 1892, Helen had an attack of typhoid fever, not over severe. During this time the delirium was of a talkative character, and she readily fell into conversation with whomsoever came near, relating her dreams, intermingled with the constant complaint of the same pain in the back of the head as in her former illness, but with almost no trouble with the digestive functions. After the convalescence from this was safely established, she was brought to me in the city and placed in the hands of two professional nurses of large intelligence, and her condition more closely watched. The improvement in all particulars was steady and admirable. The imaginative tendencies showed themselves occasionally, and were quietly argued away or ignored. The desire to do bizarre and silly things was likewise discouraged, occasional tendencies to soil herself and the bed were promptly nipped in the bud, not too roughly, and a general measure of systematic education in the decencies instituted, which very soon had an excellent effect. From being carefully directed by kind, gentle, tactful personalities, the imagination was clipped, reduced to normal proportions, and a large amount of residual common sense allowed to come to the surface. Undoubtedly much harm had been done unwittingly by the mother in unconsciously encouraging some of these poetic flights, and causeless apprehensions were not judiciously explained away; obedience was not demanded to practical matters at home, overindulgence probably given to vagaries of thought and act, and, in short, parental discipline, never the best in cases such as this, was probably rather worse than usual from a mother who was oversolicitous. July 10, 1893, my last report from this case is most favorable.

*Case II.*—Bessie A., aged 6 years, came under my care February 11, 1889. Family history good; third child; one dead of cholera infantum. B. was perfectly well in every respect until at 5 years of age had scarlatina very severely; mouth, nose, and eyes seriously affected; vomited constantly for a long time; was ill two months; the vomiting continued until quite recently, at intervals; toward the end of the illness the child was paralyzed, involving the left side. This came slowly on until complete helplessness resulted; eyes were crossed and capacity to swallow almost lost. In two months more began gradually to walk. The power was not especially lessened on either side. Five months after the first attack a convulsion occurred of a tonic character. The body twisted steadily to right, the eyes staring and fixed; the whole person rigid for nearly two hours; the eyes remained fixedly open until the following night; could not speak. A few hours after the beginning of this attack there was a clonic convulsion in which the head moved both ways; pupils at the time were widely dilated. The health slowly mended, until about three months ago began to have attacks of frenzy, complaining of a fear, as from some sudden noise, usually accompanied by the hallucination of seeing a cat. These increased in frequency until a dozen a day occurred; at other times almost none. Now the mind seems distinctly impaired in certain ways; tries to run away from home; on two occasions was lost. The body is miserably ill-nourished; the worm-eaten tongue of mucous

disease, considerable nasal irritation, the right lid eroded, slight ptosis; heart sounds muffled and distant, and slightly irregular pulse. She is very excitable; tries to romp and play with children, but needs to be controlled. I asked my friend, Dr. Randall, to examine the eyes, and he reported as follows: Left eye shows considerable H. As., but no gross lesions in the fundus. The right eye has corneal cicatrix. Right ear shows retracted membrane; the left almost complete destruction of membrane and a trace of left-sided facial paresis.

This child was kept under observation and treatment for over a year, steadily improving in respect to nervous excitability and physical health. The screaming spells steadily lessened. The following January considerable accession of trouble arose from being severely whipped. At that time the heart action was very irregular, and she needed constant systematic treatment of a tonic character, as well as tranquilizing measures. A year after being first seen had a fit, and soon after escaped from the house and disappeared for a day or two. In a year and a half a very severe convulsion occurred confined to the right side, chiefly in the fingers and eyes and mouth. No evidence of palsy followed. The knee jerk was found to be normal on both sides.

May 22, 1891, it was found necessary to place her in the Home for Feeble-minded Children. Is much more rational in many ways, but explosively emotional, and at such times uncontrollable by her mother, and a very great nuisance to the family and neighbors. Under the admirable care which she received at Elwyn, steady improvement took place, until to-day (May 10, 1893) she presents the appearance of an admirably well-grown, splendidly developed girl of 9. I have seldom seen a more perfect physique. The shape of the limbs and quality of the muscles are extraordinary. There appears to be no trouble with any of the organs, except still in the right eye. The intellectuality has not improved to any very great extent; takes some interest in sewing and hand work, such as kindergarten studies; can sing correctly; has a vile temper if aroused, which occurred rarely of late, and is then said to fight like a maniac; at times is rather destructive, but on the whole is a very good girl, obedient to teachers, and talks affectionately of them. She, curiously enough, has a very kindly regard for myself, probably because I was the only one, until she went to the home, who dominated her sharply, and even now constantly talks about me, and promises her companions that I shall be brought to see them. To-day the only peculiarities in her nervous state are slightly excessive knee jerks in both legs and a slight clonus in each of two or three beats.

*Case III.*—A. B. Female, aged 10 years. No insanity in the family. Parents living, one brother. Previous health of patient good, but always nervous and with weak digestion. One year ago and again six months later had a convulsion following an indiscretion in diet. These convulsions passed off without leaving any apparent permanent injury. About three months ago she had a series of convulsions lasting five hours, and accompanied by fever followed by a trance-like state lasting for two days. Since then she has continued in her present state. Expression vacant, indifferent, demented. No sign of affection. Habits, filthy and shameless. Irritable, but never weeps. Rarely quiet. Lies in bed, rolling rhythmically from side to side. This movement is apparently automatic. At other times she will pace the floor like a caged beast. Makes no attempt to speak, but hums a monotonous tune. Does not like to be touched. Hearing is good. Appetite is fair. Puts any object given her in the mouth. There are no palsies. The reflexes are normal. Abdominal and thoracic organs normal. Urine normal. Pupils at times dilated and react to light and accommodation. There is marked pallor and emaciation. After a year her physical condition had much improved. Mentally she is in a condition of dementia.

## ARTIFICIAL ALIMENTATION OF CHILDREN IN MEXICO.

By Dr. J. R. ICAZA.

GENTLEMEN: This is a subject that was proposed to me by the honorable Dr. Keating, worthy president of this Section of the Diseases of Children, and of which, counting upon your good will, I am going to briefly treat. According to him, it is not my part to busy myself with the different branches that may be allied in a general way to the alimentation of children, nor is it even my duty to make an analytic study of the different methods, more or less worthy of recommendation, that are employed to raise them, when, by some circumstance, they are deprived of their natural food. My mission is reduced, I believe, to telling what is done in my country in such cases. Nevertheless, although it may be a few words, I will say

something of the course pursued by the Mexican physicians in directing the alimentation of children in the first epoch of their lives; that is, from birth until the first dentition is over.

In Mexico, gentlemen, it is the general rule that the mothers nurse their children, and it is the truth that we physicians never have to tell Mexican women of the obligation they have of suckling their offspring. There they are dedicated completely, and perhaps to an exaggerated degree, to the domestic duties, and the privations and annoyances of raising children to full age matter little to them and prove a pleasing task. But when the children are left orphans, or when the mothers are unable to nourish them because of lack of health, because they have not sufficient milk or because the milk is bad, then we recommend a wet nurse, taking precautions, you understand, before trusting the child to her care, to examine her thoroughly to see if she is healthy and if her milk is abundant and of good quality. It is worthy of remark that the wet nurses always live in the house and are under the direct vigilance of the family. But if the poverty of the family or other cause prevented the employment of a wet nurse, there is no other remedy than to resort to artificial food; but we never advise this course, so troublesome and full of difficulties and obstacles, to be followed, except when we see ourselves forced to do so by exceptional circumstances. I express myself so, because the direct lactation by females of animals is very rarely done. However, in some cases goats are used, because, as is well known, they are better adapted to the purpose, as much on account of the form of their mammae and the abundance and quality of their milk, as that they easily become accustomed to take care of the children.

We now arrive at the first question: What do we do in my country to artificially nourish children? Generally milk of the cow, goat, or ass is given them. That of the cow is the most used because it is cheaper and more easily obtained. It is scarcely ever given in its crude state. It is customary to use it skimmed and boiled mixed with an infusion of yerba buena, orange leaves, tea, or some other aromatic plant, or boiled water in order not to change the taste and not to diminish the original nutriment. This mixture is made in various proportions; for children under six months, two parts of water or of the infusion are mixed with one part of milk; from the sixth to the ninth month, equal parts of milk and water; from the ninth to the twelfth month, two parts of milk and one of water; after one year, three-fourths milk and one-fourth of water, and after fifteen months pure milk is given. In administering it the bottle is often used. We have many models on the market, but the most accepted for its simplicity and for the ease in cleaning it, a most essential condition in order that the milk may not be altered in its constitution, consists of an ordinary bottle of 300 grams, approximately, the mouth of which is made of gutta percha. In the first six months a half bottle is given every three hours and after that age a full bottle in the same intervals. At times it happens that children refuse cow's milk or digest it badly and it is then given them mixed or boiled with flour, corn, wheat, or rice and it is often greatly improved by the change.

Ass's milk and goat's milk are also employed, especially the first, whose composition, as is well known, resembles that of human milk. It is more difficult to obtain and costs more. Families that are able to enjoy some conveniences have the ass in their own yards so as to be able to order milk for the child when needed, which is then taken warm and without any adulteration. I could cite many cases in which ass's milk has given positive aid in raising children. A chemical analysis shows that it is more easily digested than that of any other animal.

Some families give their children artificial preparations, such as Nestle's Lactated Food, which is composed principally of toasted bread dust, wheat flour, and milk dried in a vacuum; Hagner's Food, Liebig's Extract, or other similar mixtures. The poor often use *atole*, a drink that consists of a paste made of ground corn which is diluted with water and milk and afterwards boiled. This is a food less wholesome and nutritive than milk but easily digested.

The truth is, it is necessary to vary the food for it happens that children, like adults, have different individualities and what is acceptable to some proves nauseous to others.

I have already indicated that in Mexico it is very rare that a child is given milk or any of the preparations I have mentioned. These preparations are used more especially for mothers and wet nurses, when the milk becomes scarce, and for motherless children—in a word, for variety's sake. However, among the poorer classes, the children are often denied the breast and are given all kinds of food. If artificial feeding, conducted with great care, is always perilous, it is much more so if not done in an intelligent manner. As proof of this assertion I will say that we see every day among poor families more or less grave disturbances of the digestive organs in children prematurely weaned which are quickly cured by a return to the breast; and we see also that the children of poor nurses, badly nourished and improperly fed, nearly always perish.

---

### THE GENERAL PRINCIPLES UNDERLYING ALL METHODS OF INFANT FEEDING.

By T. M. ROTCH, M. D.

*Professor of Diseases of Children, Harvard University.*

Just as the highest aim of medical art should be directed to the province of preventive medicine, so the highest and most noble branch of preventive medicine should consist in the study of the best means and the most practical methods for starting young human beings on their life race; for preserving them from the perils which surround the early hours of existence; for giving them strength and vigor to resist the attacks which, greater and more dangerous in inverse proportion to their age, must inevitably be made upon their vitality. The preventive medicine of early life is preëminently the intelligent management of the nutriment which enables young human beings to breathe and grow and live. In fact, it is a proper or an improper nutriment which makes or mars the perfection of the coming race. Infant feeding, then, is the subject of all others which should interest and incite to research all who are working in the preventive medicine of early life. The subject is a great one and is worthy of the attention of the greatest minds of the age; worthy for the discussion of the leaders in medical thought of our Western Continent. The responsibility of introducing such a serious question before such an assemblage of advanced medical thought is a grave one. It should be taken up carefully—it must be dealt with broadly. We must acknowledge for the present, and in fact it is true, that in the status of infant feeding as it has existed up to the last few years, the average human breast-fed infant is more likely to live, the other factors of the life problem being equal, than the infant which is fed by any other method. But we must remember that the latest scientific work on this subject shows very clearly that it is not breast milk as a whole which is preëminently good, but that there are definite known reasons inherent in the different elements of the breast milk which make it the best known food. It is our province as scientific workers in this most important branch of practical medicine to year by year elucidate and make use of these elements, once covered by a somewhat mysterious veil, but now rapidly being laid bare by the search light of patient and laborious investigation. A great advance has been made in our knowledge as to what we are to copy from human breast milk and what we must achieve in preparing a substitute.

The very essence of this practical information which we have gradually acquired lies in the discovery that there is no one perfect nutriment for young human beings as a whole, but that it is the changes in the various elements of the breast milk which satisfy the demands of the individual, and thus in time suits the many to such

a degree that this protean food has erroneously come to be looked upon as one especial, unchanging nutriment. To thoroughly understand and successfully solve the feeding problem of the early months of life, a knowledge of the changes which take place in the mammary gland from many causes must be clearly kept in view. Again, the methods of modifying the milk in the human mammary gland, however limited in their scope they may be, should be practically investigated and carefully adapted to the individual according to its age and size and general physical condition. The mammary gland in its perfected state, uninfluenced by disease or nervous disturbance or by the improper living of its owner, is a beautifully adapted piece of mechanism constructed for the elaboration and secretion of an animal food. When in equilibrium it represents the highest type of a living machine adapted for a special purpose, both mechanically, chemically, physiologically, and economically. When for any cause this sensitive machinery is thrown out of equilibrium its product is at once changed, sometimes but slightly, but again to such an extent that the most disastrous consequences may follow when it is imbibed by the consumer. To state then, concisely, what I have already referred to, we should, in studying the form of nutriment which shall be suitable for the early months of life, manifestly be guided by what nature has taught us throughout many ages.

The researches of science are, indeed, especially in the subject of infant feeding, wisely directed to learning to read the truths which nature presents to us. Great progress has been made in reading these truths; what we are at present endeavoring to do is to copy them. The constituents of the nutriment which nature has provided for the offspring of all mammals is essentially animal and never vegetable. Human beings, therefore, in the first twelve months of life are carnivora. It is therefore evident that an animal food entirely and always free from any vegetable constituents has been proved to be the nutriment on which the greatest number of human beings live and the least number die. Where good breast milk, or rather one that is fairly adapted to the individual infant, can not be obtained, or, if obtained, can not be regulated by modification, it is desirable to combine the elements which good breast milks represent. For perfecting this, what best may be called substitute feeding, we must have a material which, while as closely as possible approaching the analyses of good breast milks, is also easily accessible. There is no mammal whose milk production corresponds sufficiently to human milk to render a direct substitution safe or wise. If, therefore, milk is used, the problem demands for its solution a modified milk. The mammal whose product representing a carnivorous food has been proved from the earliest ages to best satisfy this demand is the cow. Certain breeds of cows are better adapted than others to produce milk which can be used for copying human milks. For the use of this continent these breeds are the Durham, Ayrshire, Holstein-Friesien, American grades, and common natives. The infant at the breast receives for its nutriment a fluid which is fresh, sterile, neutral or faintly alkaline in reaction, which has a temperature of 98° to 100° F., and which is furnished in an amount proportionate to its age and size. It is this fluid which we should copy in every possible detail when we undertake to prepare a substitute food. We should also consider as foreign matter to be rigidly avoided, any element which we know is not to be found in the fluid which we are copying. Thus, and thus only, can we finally arrive at the proper solution of this intricate feeding problem. It would seem hardly necessary to suggest that the proper authority for establishing rules for substitute feeding should emanate from the medical profession and not from nonmedical capitalists. Yet, when we study the history of substitute feeding as it is represented all over the world, the part which the family physician plays in comparison with the numberless patent and proprietary foods administered by the nurses is a humiliating one and one which should no longer be tolerated. I would plead in the name of common humanity, as well as in that of the intelligence and scientific reputation of our profession, that this representative body of American physicians should in its endeavor to advance

the general subject of infant feeding record itself as opposed to the use of patent or proprietary foods of every description. If we are abreast of the times, if we will but recognize and do justice to the work which has lately emanated from our own profession, we surely will not hesitate to boldly relegate to oblivion the statements of the food proprietors, which on box and can, on bottle and on printed circular, attempt to stem the slow but inevitably progressing wave of scientific investigation. It may be well to bear in mind that the attempts which in the past have been made to manufacture cheap foods have been markedly failures. We must first, regardless of expense, learn to produce by modification a perfected substitute food before we should endanger the success of our undertaking by allowing the mercantile side of the question to cripple us in the use of costly methods which, however, we know to be the best. We should, in fact, remember that the nutriment which we are endeavoring to copy, far from being a cheap product, is, on the contrary, a very expensive one. It is the knowledge of how to determine the best combinations of certain elements and the best methods of accomplishing these combinations which has in the last year or two especially claimed our attention and in which we have met with signal success.

There is no doubt but what one of the most important questions connected with the preparation of a substitute food is the proper control of the primal milk supply. What that control shall be and how it shall absolutely be kept in the hands of those who by education and unselfish interest are most fitted to use their power wisely is a matter worthy of your deepest thought. The state control, as represented in Denmark, is indeed a brilliant example of what can be accomplished in this direction. Whether a similar method would prove to be the best for us to adopt has not as yet by any means been proven. The political clouds which continually obscure the highest scientific aspirations on this continent make it probable that for the present, at least, the primal milk supply can best be perfected by individual enterprise and enthusiasm.

Finally, I would call your attention and consideration to the great capacity of different infantile digestions for assimilating a variety of proportions of the same nutritive elements, and hence when introducing new methods for preparing a substitute food the necessity for providing for many prescription possibilities. The latest researches on human breast milk show that the albumin of the milk is not merely an exudation from the lymph vessels supplying the mammary gland, but that it is actually modified in the breast. We thus see that the mammary gland, besides being an elaborator and a storehouse for infant nutriment, is also a modifier. Following, therefore, nature again closely, we learn that the precise modification of an absolutely pure and fresh primal milk supply is the vital principle which should at present underlie our efforts to perfect substitute feeding, and I trust that those who will to-day take part in the discussion of this very important subject will especially enlighten us on two matters of extreme interest. First, what is the best method of obtaining a stable and perfect primal milk supply? Second, when this supply is obtained how shall it best be modified?

---

### STUDIES IN INFANT FEEDING.

By HENRY DWIGHT CHAPIN, M. A., M. D.,

*Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital.*

There are certain requisites for an infant's food before it can be recommended for general use. Thus, it must be readily procurable under the common and ordinary conditions of life; it must be digestible, nourishing, and fairly cheap. The mixing or preparation of such a food must not be too complicated. The conditions here mentioned can only be met by employing cow's milk, more or less diluted or altered, according to the necessities of the case. The following paper contains no new prin-

ciples, but is rather a record of experience in the simplest manipulation of cow's milk to make it most acceptable to the infant's stomach and digestion. The clinical experience has been principally derived from the babies' wards of the New York Post-graduate Hospital, where the infants are subjected to close scrutiny and constant weighing during periods varying from several days to as many weeks and sometimes even longer. Those who have had a large dispensary and hospital experience in artificial infant feeding among the poor can not have failed to notice the frequent tendency to atrophy. This is often so extreme as to cause death. Even in cases not so marked there is almost universally present a condition of underweight. Many unfavorable hygienic conditions favor this deplorable result, but the principal cause is the nature and quality of the food that is administered. This grave tendency toward atrophy should constantly be borne in mind in all studies bearing on artificial infant feeding.

The milk as ordinarily delivered on a given morning in New York, and doubtless in other large cities, consists of a mixture resulting from the milkings of the previous morning and the night preceding, thus being from 24 to 36 hours old. If the milk dealer knows his farmers he can sometimes induce them to put the 24 hours' milk in a can by itself, which is a gain as regards infant feeding. What is urgently needed is more scrupulous cleanliness in the handling of the cows and milk upon the farm, and quicker and more frequent methods of transportation of the milk to town in order to represent a real gain in the feeding of infants. It need hardly be mentioned that the average milk from a herd of cows is better and safer than the traditional one cow's milk. As soon as the milk is received in the early morning it is put in a tin pail or wide-mouth vessel that is covered and allowed to stand in a cool place for 3 hours. The top half only of this milk is to be administered to the infant, as advised by Dr. Meigs. This top portion is best separated by being carefully dipped off by a cup or ladle. If decanted both layers of the milk will become mixed by the lower part rising when the vessel is tipped. At the babies' wards a long glass cylinder is employed, which is graduated and furnished with a stopcock at the bottom. After standing the required time a distinct difference is noted in the two portions of the milk, which are easily separated by drawing off the lower half and reserving the remainder for the infant's use. In order to learn exactly what difference the simple process of standing would make, the two parts of the milk were analyzed, with the following results: One gallon was drawn from the bottom of the cylinder, well mixed, and a sample taken which showed:

|                     | Fat.             | Total solids.    |
|---------------------|------------------|------------------|
|                     | <i>Per cent.</i> | <i>Per cent.</i> |
| 1.....              | 3                | 12.29            |
| 2.....              | 3                | 12.44            |
| 3.....              | 3.1              | .....            |
| Mean .....          | 3.03             | 12.36<br>3.03    |
| Solids not fat..... |                  | 9.33             |

The upper portion of the milk, 1 gallon, was well mixed and a sample showed:

|                     | Fat.             | Total solids.    |
|---------------------|------------------|------------------|
|                     | <i>Per cent.</i> | <i>Per cent.</i> |
| 1.....              | 4.9              | 14.01            |
| 2.....              | 4.8              | 14.02            |
| 3.....              | 5                | .....            |
| Mean .....          | 4.9              | 14.015<br>4.9    |
| Solids not fat..... |                  | 9.115            |

This analysis shows that practically the only change on standing is a rise of fat. This, of course, slightly raises the percentage of other solids in the lower portion, since the abstraction of any constituent from a mixture raises the percentage of all the remaining constituents. The upper portion contains, roughly, 5 parts of fat for every 3 parts contained in the lower portion. The minimum of fat allowed for genuine milk is 3 per cent. The increased amount of fat thus procured, in the part of the milk to be used, represents a real gain in feeding the infant. The newer analyses of milk do not confirm the older view that cow's milk contains more fat than human milk, but rather the reverse. Thus Prof. Leeds found, upon analyses of 43 samples of woman's milk, an average of 4.013 per cent of fat, while upon analyses of 11 samples of whole market milk the average percentage of fat was only 3.75 per cent. König finds the average of fat in woman's milk to be 3.90 per cent, and in cow's milk 3.66 per cent. Prof. Rotch places the average of fat in both cow's and woman's milk at 4 per cent. As cow's milk has to be more or less diluted before being administered to the infant, the necessity of starting with a preparation that is rich in fat will be apparent. The next step to be taken is to see that all fermentation in the milk is stopped.

Cow's milk, as ordinarily procured, must be treated for its biological as well as its chemical properties. The well-known process of sterilization aims to fulfill this object. Partial sterilization, or pasteurization, to the point of killing the germs only, is necessary and desirable. The high and continuous temperature required to destroy spores produces various unfavorable changes in the milk. Practically, all that is required is to submit the milk to sufficient heat to destroy the bacillus of lactic-acid fermentation which causes the souring of milk. This bacillus has been described as of small oval form, occurring singly and in pairs. It is easy, by prolonged and repeated applications of high temperature, to keep milk indefinitely from souring. By reheating once or twice, it can be kept for months without any sign of acid fermentation. Such milk, however, is by no means fit for administration to the infant, as the fat collects in masses and changes have taken place in the albuminoids. The casein is altered, the milk remaining more or less liquid in the stomach, as the action of the stomach acids and of the lactic ferment on the casein of sterilized milk is incomplete. Analyses of excrement show more nitrogen and more fatty acids after feeding with sterilized milk than with raw milk. Not only is the digestibility of the milk diminished by long heating, but the necessity for it indicates so much bacterial impurity that their excreta, which can not be rendered harmless by heat, may cause poisoning. It has been found that milk well sterilized will, after a certain interval of time, undergo a species of decomposition with an alkaline reaction. Dr. Koplik states that the alkaline fermentation has not been investigated to such an extent that we can with certainty pass upon the deleterious or non-deleterious effects upon infants of the products of this decomposition. It is enough to know that it takes place, and certain alkaloidal elements are very slowly but surely produced. Accordingly, this writer condemns the storage of sterilized milk and its subsequent use after prolonged periods, and I concur with this opinion. Simply sufficient heat must be applied to the milk to keep it sweet until the next supply can be procured. An ordinary double boiler, such as is found in every kitchen, will meet all the requirements of average heating. The Arnold steam cooker may prove more convenient, and Freeman's pasteurizer is handy and efficient. As a rule, 15 minutes' heating is sufficient with the bottles well plugged with cotton. The addition of a 1 per cent solution of peroxide of hydrogen is a safe preservative of milk for some hours, when heating is undesirable or not convenient. If more scrupulous care were exercised at the source of the milk supply, and the impurities completely separated by the centrifugal process, in the great majority of cases no means at all for preservation need be employed, and an advance in this direction is urgently needed.

We still have facing us the old and difficult problem of how to act best upon the

tough, leathery curds of cow's milk as to make them most acceptable to an infant's weak digestion. Not only are the albuminoids much greater in amount in cow's milk, but the portion coagulable by acids is greater than the non-coagulable part, while in woman's milk the non-coagulable part much exceeds the coagulable portion. Hence the dilution of cow's milk, while reducing the albuminoids to a proper percentage, does not necessarily render the clot sufficiently soft to be readily digested by the infant. The question whether the size of the curd stands in any relation to the substance used as the diluent has been disputed. It has been taught that by adding gruels of the cereal grains to the milk the clot is mechanically attenuated. Dr. Rotch states, on the contrary, that practically the size of the curd depends simply on the dilution of the albuminoids and not upon the particular menstruum used. Clinical results, however, point plainly to the utility of diluting with barley water, except in very young infants, and I believe the beneficial effects are, to a certain extent, due to a lessening of the compact character of the clot. In order to test this, the following experiment was made by Dr. Eiloart: Equal parts of milk and barley water were taken, and 0.1 gram of hydrochloric acid was added to 100 c. c. of the mixture. This strength was employed, as in gastric juice there is 0.2 gram of hydrochloric acid to 100 c. c. of fluid, which, on dilution by the contents of the stomach, is weakened somewhat, so that 0.1 gram is a fair estimate for the experiment. Some albumins require 0.2 per cent hydrochloric acid added to pepsin in artificial digestion to obtain the best results, but casein and vegetable albumin are digested best by 0.1 per cent of hydrochloric acid.\* This experiment showed the casein formed in finely divided clots. Next, equal parts of plain water and cow's milk were taken and 0.1 gram hydrochloric acid added to 100 c. c. of the mixture. This showed larger clots than before. A number of repetitions gave similar results, using various coagulating agents when plain water and thin gruels were used as comparative diluents. When rennet alone was used as the coagulating agent, the results were so different from those obtained when hydrochloric acid was used with the rennet that recourse was had to the stomach itself, with results given in the accompanying paper by Dr. Eiloart. The disadvantage in the employment of wheat or barley flour consists in the large proportion of starch contained in these grains, which may be great in very young infants. This starch may be rendered more soluble and easy of assimilation by heat or diastasic action. In many cases the effect of prolonged heating upon barley and wheat flour seems to have a beneficial effect, particularly when there is a tendency to diarrhoea. The good results of the old flour ball, made by prolonged boiling of the wheat flour in a bag, have long been recognized. But the heat so applied does not produce its beneficial effect by chemically changing the starch, but probably from some physical alteration which renders it more effective as a diluent.

The effect of dry heat upon starch is to produce changes into soluble starch, retro-dextrin, achroödextrin, and finally a small percentage of dextrose and maltodextrin.† The higher dextrans are more soluble. Starch does not begin to dextrinate until 250° F. is reached, and this temperature should be maintained for several days if there is any quantity to be changed. At between 350° F. and 400° F. dextrination may take place in a few hours. It is evident that such a high temperature can not be maintained by any domestic process. If put into an oven the flour will soon be scorched or burned. An interesting experiment was made by Dr. Eiloart upon barley flour that had been heated for a week in an ordinary double boiler. The water in the under vessel was allowed to boil for a week, with the exception of a few hours at night, the dry flour in the upper vessel being thus exposed to as high a constant temperature as possible under the circumstances. An analysis of the unheated meal taken from the same barrel yielded two-thirds more sugar and one-quarter more dextrin than the heated meal. The cause of this is that the diastase, whose function it is to convert starch into sugar and dextrin, is partially paralyzed by heat, the fer-

† Stohmann and Kerl. *Muspratt's Chemie*, Bd. 11, Braunschweig, 1889.

ment undergoing this change at about 175° F. This method of acting upon the starch was accordingly abandoned, and the necessary change effected easily and quickly by means of diastase. Starch treated with diastase is split up quickly into maltose and dextrin, and the longer the action is continued the higher dextrin will be formed, such as achroödextrin and maltodextrin. After a number of experiments and analyses, Dr. Eiloart devised a receipt, for which I am indebted to him, and which has been used at the babies' wards, consisting of a mixture of barley or wheat flour treated with diastase,\* the temperature of digestion being regulated by the addition of hot and cold water in proper proportion. The complete description of the process will be found in the accompanying paper.

## A FOOD FOR INFANTS, WITH EXPERIMENTS, CHEMICAL AND PHYSIOLOGICAL.

By ARNOLD EILOART, PH. D.,

*Director of the Chemical Laboratory, New York Post-Graduate Medical School and Hospital.*

The experiments here described were intended to throw light upon two problems. The first was the formation from cow's milk of a curd resembling in fineness that from woman's milk. The importance of this seems evident,† and Uffelmann‡ has shown that in artificial digestion the proportion of peptone formed was greatest when the curd was loosest. He recommends mixing cow's milk with three-fourths its volume of 0.2 per cent hydrochloric acid in order to make the casein like that of human milk. Munk,§ having tried Scherff's process of sterilization (heating to 100° C. under 3 atmospheres pressure), states that milk so treated clots in the stomach itself in flocks like woman's milk, not in compact masses like ordinary cow's milk. It seems unlikely, however, that these methods will come into general use, and the following work has been confined to testing diluents which are everywhere available. The result of a preliminary investigation was surprising, for it appeared that the fineness of the curd depended more on the curdling agent than on the diluent mixed with the milk. Thus, with rennet, mixture A curdled finer than mixture B, while with hydrochloric acid, 1 per cent, mixture B curdled finer than mixture A.|| Hence the test-tube experiments, which have constantly been quoted to show the effect of various diluents, must be abandoned and the infant's stomach itself must be consulted to decide what mixture will curdle finest in that stomach. Accordingly, the mixtures to be tested were administered to infants, and after a short interval withdrawn by means of the stomach pump. I am indebted to Dr. Chapin for the opportunity of carrying out these tests in the babies' wards of this hospital.

In the following table I have used figures to indicate degrees of fineness of clot, calling the finest curd 1:

\* Maltine was the preparation here yielding the diastase.

† Ellenberger and Hofmeister, however, object to the fine curd of sterilized milk, because it may pass too quickly through the system and thus escape complete digestion (*Molkerei Zeitung*, 1892, 6).

‡ Pflüger's Archiv, 29, 399.

§ Deutsche Med. Woch., 1881, No. 36.

|| Mixture A was milk and water, āā; mixture B was milk and barley water, āā. With a mixture of hydrochloric acid and rennet the result was the same as with the acid alone. In every case the volume curdled was 100 c. c.; very small quantities fail to show the differences in the curd.

TABLE I.—*Showing fineness of clot and acidity of stomach contents after feeding with milk and various diluents.*

[Fresh milk was used except where sterilized is mentioned. Throughout this work the regularly prescribed malt preparations were used as the source of the diastase.

\* Sterilized.

The figure 4, indicating the very coarse clot sometimes obtained with hydrochloric acid (0.1 per cent), is absent from the record of stomach clots, although the percentage of acid in the stomach, calculated as hydrochloric, sometimes rises almost to 0.1 per cent. The chief conclusion to be drawn from the stomach experiments is that the coarseness of curd increases with the percentage of acid. Thus the finest curd (called 1), which was only once obtained, occurred when the acidity was 0.0467 per cent; the curd next in fineness occurred in 6 cases in which the mean acidity was 0.062 per cent; whereas for curd 3 (rather coarse) the acidity averaged 0.072 per cent (mean of 9 cases).

So far we have left out of account the diluent used. If we arrange the results so as to show the number of times a given diluent produced a curd of the second or third degree of fineness, we find that water gave clot 2 once, clot 3 four times; barley water gave clot 2 three times; diastase, with or without cereals, gave clot 2 twice, clot 3 four times. So far the results proclaim barley water to produce the finest, and water the coarsest curd. But when we take into account the acidity in the different cases, we find it to average in the three barley-water experiments only 0.053 per cent, while in the four water experiments it is 0.077, and in the case of the diastase preparations, which yielded curds almost as coarse as the water mixtures, the acidity is nearly as high, viz, 0.071 (average of the 6 cases). The good results apparently due to the barley water may, therefore, be due in reality to a low percentage of acid. On the other hand, further experiments may show that barley water itself causes the low percentage of acid.

The influence of the concentration of the curdling agent is well seen in the following experiment made with an adult: A mixture of 500 c. c. milk with 500 c. c. water at blood heat was taken. Two minutes afterward 360 c. c. were pumped out from the stomach; 6 minutes later 400 c. c. were removed; 8 minutes later the rest was removed. The first portion was curdled so fine that close examination was needed to see that it was not homogeneous. The second portion was fine, but coarser than before. The third portion consisted of yellow liquid with some quite coarse clots; the gastric juice was no longer diluted by excess of milk.

#### EXPERIMENTS WITH CEREALS.

Whatever be the part played by barley water in the stomach, it has made good a place in infant feeding, which indicates that benefit is derived from its use. But it seems probable that any such benefit is largely neutralized by the great proportion of starch which all cereals contain and which the infant economy is ill adapted to digest. It is true that infants' food may be bought in which the starch has been dextrinized by heat; but these are expensive. The object was then to devise a household process for preparing at a minimum cost, and with materials everywhere available, a digestible food containing with the albuminoid constituents of the grain, carbohydrates in a soluble form and but little of the insoluble starch. At the same time excess of sugar was to be avoided. This necessitated the conversion of the starch into dextrin, or into dextrin with a moderate proportion of maltose. Attempts to dextrinize the starch by heat showed that this method is not adapted for household use. Barley cakes baked many hours yielded only 23.3 per cent of soluble matter. Rusks ("Zwieback") as bought were further baked, but only 16 per cent could be made soluble. To facilitate the dextrinization by providing an acid, barley cakes were made with buttermilk and well baked, but the soluble matter was then only 20.07 per cent. Rusks moistened with buttermilk and baked at 120° C. yielded 18.88 per cent of soluble matter. These results necessitated a resort to diastase as the converting agent. O'Sullivan has shown that maltose and dextrin are the only products of the action of diastase on starch, and that the proportion of maltose to dextrin depends on the temperature. This proportion may be kept down to about 18 per cent by employing a temperature just below that which destroys the diastase and by stopping the action before the diastase converts the dextrin first

formed into maltose. To adjust the temperature, hot and cold water were mixed in varying proportions. The temperature of the hot water was the highest which can be attained in the inner vessel of an ordinary double boiler of tin or enameled iron when the water in the outer vessel is kept boiling; this temperature does not vary much with the size of the boiler and is about  $91^{\circ}\text{C}$ . The diastase was allowed to act on gruels made with starch, with wheat flour, with barley meal, and with oatmeal. The line of action, the quantity of water, and the temperature (proportion of hot to cold water) were varied, and more than twenty analyses were made to determine the proportion of soluble matter and maltose formed in each case. As the result of these experiments a most simple process was arrived at, by which in any kitchen a cereal food may be made containing three-fourths of the solid matter in a soluble form and having more or less sugar (maltose) as desired.

For a food containing about one-third of the solid matter in the form of maltose, the following recipe may be used:

*Recipe I.*—Materials: Wheat flour or barley meal, 2 ounces (2 tablespoonfuls heaped as high as possible); water, 56 ounces (a quart and three-fourths); extract of malt, half a teaspoonful or a small teaspoonful.

Process: With 30 ounces (a scant quart) of the water make the flour into a gruel, boiling 10 minutes in a double boiler. Take out the inner vessel and add the rest of the water cold, the malt extract being dissolved in the last few ounces added. Let it stand 15 minutes. Put back the inner vessel and heat again in the double boiler 15 minutes. Strain through a coffee strainer of wire gauze.

If for any reason it is desirable, and in cases of diarrhœa, to give a smaller proportion of maltose, the following recipe is used, and we get a food containing only one-fourth of the solid matter in the form of maltose:

*Recipe II.*—Materials as in Recipe I. Proceed as before, but reserve only 1 pint of the water for adding cold. After adding the cold water with the malt extract dissolved in the last few ounces of it, let it stand only 3 minutes instead of 15 minutes. Then heat 10 minutes in a double boiler and strain. To make the gruel well and quickly, beat the flour with very little water. A little beating with little water is better than much beating with much water. Beat smooth, therefore, while the paste is still almost a dough; then add cold water to make a thin paste, and to this add the rest of the first part of the water boiling hot, with stirring. If these directions are followed, very few lumps will remain on the strainer; in fact, only about 5 per cent of the meal need be lost in this way. The water in the outer vessel of the double boiler must be kept boiling throughout. Whichever recipe is followed, the food should be taken mixed with milk.

Digestion tests: *Cæteris paribus*, the more of a food is dissolved in the stomach, the more digestible is that food said to be. Therefore if we find in the stomach contents, after giving milk with malted food, a larger proportion of soluble matter than when milk is given with unmalted food (due allowance being made for the larger proportion of soluble matter in the malted food itself), then we may say that the malted mixture is the more digestible of the two. In order to test this, experiments were made with three infants and the following results were obtained:

*Ratio of soluble to total matter in stomach contents.*

| Subject. | With malt-<br>ed food. | With un-<br>malted |
|----------|------------------------|--------------------|
| 1.....   | 0.65                   | 0.58               |
| 2.....   | .74                    | .61                |
| 3.....   | .58                    | .64                |

The difference is appreciable (later results indicate that this was due to the short time allowed for digestion, which never exceeded a few minutes in the above cases). A comparison was next made between the two foods without admixture of milk,

The process now followed was this: The stomach of a healthy man was washed clean with lukewarm water—i. e., the washing was continued till the water from the stomach ran perfectly clear. Then a definite measure of gruel containing a known weight of solid food was drunk in five equal draughts with an interval of a minute between each draught. After a certain time the stomach was again completely washed; the washings were made to a given volume. The total solid matter and the dissolved matter were determined; the difference gives the matter undissolved. Experiments were made with 3 men, all free from any disorder of the stomach. The food prepared with diastase was given one day and the plain gruel the next. Although the amount of either food disappearing in a given time varied considerably, the results were sufficiently concordant to decide the question at issue.

TABLE II.—Showing proportion of food found in stomach after various periods of digestion.

[A(—) under "diastase" indicates that none was given. A (+) indicates that the diastasic extract was used in the proportion given in the recipe.]

Experiments 1 and 2, which were made without previous washing of the stomach (no food having been taken since the night before), agree fairly well with the others, showing that the digestive process is not rendered abnormal by previous washing. In the case of subject No. 1 the amount found in the stomach was constantly greater when the diastase was omitted; the percentage of food taken which was left in the stomach after 40 minutes being, without diastase, 52.02; with diastase, 29.2. This means that of 100 parts of food taken, 100 — 52.02, or 47.92, were absorbed in the one case, and 100 — 29.2, or 70.8, in the other; so that with the diastase nearly half as much again was absorbed as without it. Of the solid matter found in the stomach more than twice as much was found to be undissolved when the diastase was omitted as when it was used.

With subject No. 2 a shorter time (24 minutes) was given for digestion and no marked difference appeared between the two foods; but when the time of digestion was extended to 40 minutes the malted food again asserted its superiority, the amount of this unabsorbed by the stomach being only one-third the amount of plain food unabsorbed. In the case of subject No. 3 the difference in favor of the malted food was made manifest in 25 minutes. In every case, therefore, digestion was more rapid with the malted than with the unmalted food. Thus the physiological evidence confirms the chemical evidence in favor of the food prescribed. Finally, clinical experiments with the soluble food, made according to recipe No. 1, have given as good results as any system of feeding employed at the babies' wards of the Post-graduate Hospital, as detailed in the accompanying paper by Dr. Chapin. It is intended to employ the method of quantitative stomach washing in other cases, as it seems adapted for testing foods and digestive ferments in general.

This food can be easily and cheaply prepared in any household and while the starch is changed to more soluble forms, there is not an excess of sugar. Herein it is superior to the various Liebig's foods. The nutritive value of the albuminoids is likewise not lost sight of. Either barley, wheat, or oatmeal may be thus treated, the principal difference being the varying proportions of fat contained in these grains. According to Dietrich and König, the percentage of fat is as follows: Barley, 2.09; wheat, 1.55, and oats, 6.09. This may be borne in mind in prescribing for diarrhoeas and the various forms of indigestion. The effect of malt upon milk is to favor its digestion and assimilation. Garup Besanez, a German authority on malt, has found a ferment in the germinated seed of vetches, hemp, flax, and barley, which very energetically converts starches into grape sugar and albuminous substances (fibrin) into peptones. It was afterwards found that diastase has no action upon albuminoids; but peptase, which is generated in germinating grain at the same time and under the same conditions as diastase and practically they can not be separated, acts upon proteids slowly at low temperatures. This substance is an analogue of the vegetable proteolytic ferments found in pineapple juice and the papaw plant.

The actual results obtained from the use of food thus prepared in the babies' wards have been good, considering the class of cases treated. During May, June, and early July, 37 infants suffering from various degrees of gastro-intestinal irritation and inflammation and from 1 to 10 months old, were thus fed. Seventeen increased slightly in weight after a week or so, 16 lost a little in weight, and 4 remained stationary. As is well known, the loss of weight in gastro-intestinal affections during infancy is usually well marked, and is exceptionally rapid in hospital and institution infants. So extremely susceptible are young infants to hospitalism that they invariably lose weight after a certain interval of time, and will die of inanition under any system of artificial feeding unless removed in season.

A baby admitted May 26, 1 month old, having had convulsions from gastro-intestinal irritation, exemplifies this fact. The weighings are registered as follows: On admission, 6 pounds 1 ounce; May 30, 6 pounds 4 ounces; June 2, 6 pounds 6 ounces; June 6, 6 pounds 8 ounces; June 9, 6 pounds 5 ounces; June 13, 6 pounds 2

ounces; June 16, 5 pounds and 10 ounces; discharged. The gastro-intestinal irritation subsided and the baby did well on its food, but at the end of two weeks it began to show the effects of hospitalism, although there was no vomiting or other sign of indigestion. When sterilized milk, diluted to the proper point with water, limewater, or plain barley water, has been used, there is almost invariably a steady and slow loss of weight from the first, so that the change so often noted upon malt-ing the preparation can not fail to be gratifying.

Dr. Judson C. Smith, who is the district visitor for the hospital, seeing a certain number of the cases after they have been discharged, tells me he has used the extract of malt to peptonize milk about one year, both for infants and adults, with very satisfactory results. Babies from 4 months to 1 year old, when losing weight on other methods of feeding, have usually gained flesh and improved in every way on milk prepared with malt. One tablespoonful of malt is added to a pint of milk, which is heated from 20 to 30 minutes and then brought to the boiling point. The milk is then diluted with water according to the age of the infant.

---

### THE PRODUCTION OF COW'S MILK DESIGNED FOR INFANT FEEDING.

By HENRY L. COIT, M. D., of Newark, N. J.

Science is about to conclude that the accidental impurities in milk, together with the defects in its nutritive values, are among the greatest causes of death to mankind. Milk, as a food, seems to be indispensable to the human race, supplying, with water, both meat and drink in early life. It is therefore of the greatest importance that we, as physicians and sanitarians, should establish a strict surveillance over the sources of supply. The perils growing out of a defective food supply appeal with special force to the physician and, through his clinical observations, are usually first apprehended by him. The great importance of cow's milk as an article of food, its universal use in all periods of healthy life, its necessary use in the sick room, its rapid deterioration at ordinary temperatures, its liability to absorb, develop, and convey the material causes of disease, make it imperative that its production and its sale be subject to the most careful scrutiny, and that measures be adopted whereby qualified persons shall enforce a proper care of the animals, prevent unsanitary surroundings, the gross neglect of cleanliness, and the fraudulent practices which, in many instances, characterize its production.

If physicians were more generally informed concerning the need for concerted action in this matter, we believe it would not be long before the now fatal results to man from impure, infected, and defective cow's milk would be greatly limited; and the mortality from tuberculosis, so largely due to our association with the bovine species, and the fearful havoc among infants would be narrowed within bounds which would not strike terror to our hearts.

In the present state of affairs it has become necessary that the medical profession should resort to active measures to protect their own interests and those of their patients against the horde of dangers which menace the life of our race through this one product alone. This is evident in the United States at least, from the fact that the larger and more powerful commercial interests are so closely bound up with the 4,000,000 dairy farmers, three-fourths of whom contribute something to our milk supply. That a very radical reform is needed in the production of cow's milk is conceded by all who, by their clinical experience, have been obliged to solve the problem of artificial infant feeding. This is also shown by a careful study of the mortality rates from among children under 1 year of age, a very large proportion of whom die of nutritional disorders, directly traceable to unwholesome milk. When it is considered that this infant mortality comprises about 30 per cent of that occurring in all ages and from all causes, we can not escape the conclusion that the

medical profession, and especially those who are equipped for the warfare, have an important duty to perform. Were it not that the foregoing was a sufficient reason for instituting a change in dairy methods, the fact that cow's milk is so generally employed for clinical purposes would amply justify such a course. Physicians very often fail to secure desired results in their work because of impoverished milk; it is therefore no less an important medical feature of the subject that so large a proportion of those under our care must be fed upon this article alone.

The current injurious practices which are common at the dairy are very numerous and are found at every step of the production from the breeding of the animal to the delivery of the product. Chief among them are those pertaining to the housing and care of the animals, the feeding of the same, the careless methods of collecting, handling, and cooling the milk, together with the total disregard of its delicate nature in transportation. It is difficult to understand why the dairy cow, which is so universally employed for human food, should receive relatively so little care when other domestic animals are so cautiously guarded. It is a practice so rare as to be remarkable that the milch cow is housed and kept as comfortably or groomed and cleaned as carefully as the horse. As to the feeding, the cow, the most valuable domesticated animal from an economic point of view, is the only one that is fed on refuse materials. The injurious and fatal consequences of this universal custom are too apparent to require comment; and to those who are not familiar with the facts the prevalence of these evils is astonishing when inquiry is made. As to the expedients resorted to by those who for commercial ends would utilize the waste byproducts, nothing too strong can be said in condemnation of their methods. By far the most prominent substance of a questionable character used for feeding cows to-day, especially near cities, is brewers' grains, known as beer or ale grains. There are probably few dairymen near large cities who do not use it to some extent. It is supposed to increase the flow of milk, which it does by augmenting the bulk of the output about 30 per cent. The cost is small, being in summer about \$3 a ton, and on this account it is employed. It is wet when sold, contains 80 per cent of moisture, easily undergoes putrefactive fermentation, and is often given to the cows in this condition. The original 70 per cent of starch and dextrin has been removed from the barley in the malting process, leaving nothing of a nutritive value but 10 per cent of proteids (the gluten) together with the cellulose. The effects of this diet are to impair the digestion of the animal, lower her nutrition, and probably to render her an easy prey to tubercle. On the milk the effect is a product which has poor keeping qualities and when it is used in large quantities materially alters its constitution. We are convinced that our failures with this milk in infant feeding are due to the rapid changes which uniformly occur in it and which are probably due to the unstable character of the fats which it contains. These volatile fatty principles, being easily broken up in the alimentary canal of the child, liberate the fatty acids which act as irritants. There is no dearth of suitable feed and fodder for the milch cow and a synthetical mixture made of waste materials is not calculated to appeal to the ordinary ideas of correctness and is certainly not permissible when the object is the production of food designed for the most delicate human organism.

Physicians can not afford to make concessions in these matters; that which they require can not be gained in this way; any indorsement of the use of waste byproducts for reasons of economical expediency, even when modified, would be misconstrued by milk producers and interpreted to palliate their use in any condition.

Between production and transportation a host of evils have arisen; yet none are more flagrant than the neglect of those commissioned to guard this all-important dairy product at our door. The milk inspector, with his local board of health behind him, are not, we think, efficient. With all their autocratic powers they do little to improve the milk supply in large cities. While these officers are handicapped by the lack of a proper State supervision at the sources of supply, yet they could set a safer

and more rational guard against impure milk than simply its specific gravity and its total solids. Milk must be poor in the extreme, in appearance, keeping qualities, and nutritive values to be quarantined by the inspector in our cities. Indeed, a large part of the milk now received passes without question the blockade of the local officer and yet it is positively unfit for the diet of the infant.

For unexplained reasons, the advance in civilization has been coincident with the failure of the race to nourish its young, and to-day artificial feeding has become an important factor in the work of the clinician. When we remember that an infant consumes during its first year about 500 quarts of milk, and that it requires but a slight variation in the conditions of milk to determine many of the fatal diseases incident to this period, not only are clinical standards essential, but a direct relation is established between the character of the food and infant mortality. Hitherto there have been no uniform clinical requirements of cow's milk from the standpoint of infant feeding. Physicians have been too much occupied through the literature of the manufacturing vender with problems of dextrose, maltose, saccharose, unconverted starch, vegetable fat, and disintegrated milk fat to give serious attention to more rational methods.

If we would obtain uniform results in the nutrition of the young, certain conditions of purity in milk are demanded and must be maintained without variation. It is well, therefore, that we should consider our needs as touching this basis for rational infant feeding, since it is a matter which affects our interests at so many vital points. We are on the threshold of a revolution in infant feeding, and while for several years the manufacturers of artificial infant food have been engaged in efforts to humanize various elements of the lower kingdoms, the profession have been chiefly occupied in trying to harmonize all the discordant views arising from the horde of irrational methods that have thus been foisted upon our attention. This state of things is fortunately being changed. More rational and scientific inquiries are now in progress; so that to-day those who have followed the more recent workers in this field and have adopted the results of their laborious work have been amply repaid. In order to fulfill the needs of infancy and childhood in the present state of our knowledge, three conditions of purity in cow's must be unfailing.

*First requirement.*—Absence of microorganisms in milk, especially of the pathogenic varieties. This may be easily accomplished so far as disease-producing bacteria are concerned, but germ-free milk has never yet been made practicable. When it is brought about it will be through a reform in the collection and handling of milk, and will include not only the personal cleanliness of those who draw it, but scrupulous care in sterilizing all utensils and milk containers, together with an atmosphere made clean by freeing it from the dust derived from the animal or her immediate surroundings. Microorganisms are found in all milk after it is drawn. Over forty varieties have been isolated from a single specimen of otherwise normal milk. They are never present in the udder except as found when the animal is diseased. Therefore they have their origin in outside sources, namely: The hands of the milker, the udders of the cow, the dust from hay or straw under the animal's feet, the loft and ceiling above, from the air which is constantly in motion, and the dirt left in improperly cleaned milk containers. These bacteria could not have a more favorable medium for their growth and multiplication than fresh milk. The conditions of warmth, moisture, and an animal secretion combine to favor their development. Along with the poisonous ptomaines they are capable of producing, these bacteria are, by their presence and growth, the cause of the various fermentations which occur in milk. Ordinary cow's milk of fair keeping qualities contains about 4,000 bacteria in a half cubic centimeter; ordinary store milk from cans has been found to contain from 38,000 and upward in the same amount of fluid. It will be a great achievement if these can be eliminated from the milk and we can obtain that which will keep without extraordinary care. Surely infant mortality must thereby be materially decreased. Pathogenic bacteria are often conveyed through the medium of milk

and it is probably true that no agent carries a greater variety. In this way tuberculosis is spread and the extent of the havoc with life from this source will probably never be known. This particular danger assumes greater magnitude when we remember that probably 30 per cent of the dairy herds in this country have one or more tuberculous cows among them. It is likewise clearly established that scarlatina, diphtheria, and typhoid fever are brought from persons who, either recovering from the disease or associated with it, are at the same time engaged in handling milk, or from untidy milkmaids who, between the milkings, are attendants on persons sick of these disease while they are prevalent.

*Second requirement.*—A constant and unvarying resistance to change during the first sixty hours after it is drawn. The changes occurring in cow's milk are determined by conditions surrounding the collection, handling, cooling, and care of the milk at the dairy farm, and while the lactic fermentation can not be long delayed, even by the greatest care, yet it is a want of proper precaution that brings about these early changes. The normal temperature of the cow, and therefore of fresh-drawn milk, is about 100° F. To insure its keeping qualities is to prevent the growth of bacteria. This is best done by quickly reducing its temperature with ice to about 45° F. and maintaining it at this point until used. Thus treated in clean vessels, milk will keep several days. Several samples of ordinary superior milk submitted by myself to Prof. Albert R. Leeds, Ph. D., were kept by him in his laboratory refrigerator for eleven days without change, the temperature of the chest ranging from 34° to 54° F. Where well-water only is available for cooling purposes, the above conditions can not be brought about, since well-water has an average temperature not above 48° F, and with it milk can not be reduced and maintained below 54° F. The cooling of milk immediately after it is drawn is probably the most efficient means known for retarding its fermentations, and it follows that since cold prevents the growth and the activity of bacteria, the earlier the cooling is effected the longer the milk will remain without change.

*Third requirement.*—A constant and unvarying nutritive value of known composition. This can doubtless be realized through an intelligent feeding of the animal, based upon chemical researches, conducted with a view to an adjustment between breeds, their feeding and the product required. The diet of the milch cow in its bearing upon the constitution of her milk has been studied chiefly with reference to the economical side of dairy farming. At agricultural experiment stations the objects have been to determine the cost of foods. Little has been done with reference to the effects of various foods upon the ultimate nutritive values of the milk. That due attention must be paid by the feeder to the particular purpose for which the cows are kept is conceded by all who are familiar with the subject. Thus for butter, for cheese, or for infant feeding, a special and accurate adjustment of nitrogenous substances and the carbohydrates must be observed with reference to the product required. This is accomplished by a proper admixture of grass, hay, fodder corn, and various tubers with solid cereal grains of different kinds ground into meal. The cheap and exhaustive foods used so largely to increase the milking capacity of the cow do not even approximately fulfill these requirements.

The most variable constituents of milk are the fats. The sugar and albuminoids are the most constant elements of its composition, so that in looking for dangerous modifications in milk chemists would do well to examine more closely into the nature of its fatty compounds, especially the volatile principles which so easily undergo changes. Although the sugar and mineral salts are quite uniform in all milks, the remaining serum solid known as casein may in different breeds vary as much as 2½ per cent, which would seriously affect its value in infant feeding. The high percentage of albuminoids has been the chief obstacle in the way of a more general use of cow's milk in feeding. The methods in vogue for diluting it in order to make it correspond to woman's milk are somewhat difficult when these elements are higher than 4 per cent. It seems, therefore, that any

method that promises to maintain the fat and sugar percentage, and yet reduce the casein, is desirable when the milk is to be used for infant feeding. The writer has had an opportunity of demonstrating the utility of a method which we commend to your careful attention. The reported analysis of milk from the breeds usually employed show the albuminoids to be uniformly in the proportion of from 4 to 5 per cent. By making a combination of a thoroughbred Jersey, a thoroughbred Holstein, and two common American grades, the first giving a milk rich in fat, the second a milk rich in sugar, and feeding the animals with a view to reduce the albuminoids, we obtain a result when the milk is mixed which we believe to be valuable. The following analysis made for the writer by Prof. Albert R. Leeds shows that the combination in this instance reduced the albuminoids to 3.36, while the fat and sugar are maintained at a normal high standard. A good feature of this milk is that it approximates more closely to woman's milk in its color, its total solids, its taste, and its reaction, which is neutral. The results of the experiment are offered as a basis for future observations, and also suggestive of a possible means of securing an ideal milk for infant feeding. The analysis as made of 24 samples, submitted on June 7, 1893, was as follows: Color, white; smell, sweet; taste, sweet; reaction, neutral; specific gravity, 1.030. Water, 86.88 per cent; total solids, 13.12 per cent; fat, 4.39 per cent; sugar, 4.42 per cent; albuminoids, 3.36 to 3.60 per cent; ash, 0.71 per cent.

In seeking a remedy for the difficulties which surround the milk supply, especially in large cities, we find that it must lie within three possible lines of action.

*Legislation.*—This is a common channel through which to appeal for reforms; with the question before us, however, our efforts have hitherto been unavailing. Legal enactments will not afford us the needed relief, since their passage have so often resulted in their being embalmed in the statute books. These laws would be sufficient if they were administered; but that they are not effectual is apparent to all. Our legislative bodies seem helpless when their dictum runs counter to commercial interests.

*Public opinion.*—This is always variable and capricious and through the influence of the public press is largely molded by vested interests. As a force to be used for reform, it is therefore unreliable. Moreover, the public are proverbially lax and indifferent with reference to matters connected with sanitation and hygiene. Destruction of property arouses alarm, but a sacrifice of life on the altar of greed or ignorance is not sufficient to awaken the concern of the masses.

*Medical supervision.*—The physician is the proper custodian of matters effecting public health; he is also the only proper agent to meet the conditions which menace human life. His knowledge of the causes and sources of danger best equip him with the means of warfare against current evils of this class. The feeding of the young in infancy and childhood, the approach of infection, which in many instances calls for unusual judgment in the selection of their food, and the many clinical relations of the milk supply, all combine to impose upon the physician important responsibilities, and to make him the proper supervisor of milk production where it is designed for his purposes.

In order to secure all that we desire in cows' milk for dietetic purposes, namely, freedom from bacteria, reliable keeping qualities, and uniform nutritive values, we propose the following plan, whereby the above-mentioned conditions may be acquired under our own supervision. This plan, which is now about to be put in practical operation by a medical commission organized by the writer in Essex County, N. J., includes three general requirements, each of which is essential, and we believe, if taken together, will establish a reliable safeguard:

(1) That physicians give their practical encouragement and support to labors conducted by a commission of medical men, selected from their own number, who shall endeavor to secure a supply of milk produced under such regulations that purity may be assured.

(2) That approved and trustworthy dairymen, possessing honor, financial ability, and dairy facilities, shall be induced, by reason of promised medical support and the increased price of their milk, to conduct their dairies, and collect and handle the product in conformity with a code of requirements made by the aforesaid medical commission and imposed by them in due legal form. This contract between the commission and the dairyman under their patronage shall be stringent and binding. It shall include ample sureties for its fulfillment, the necessary forfeiture clauses, a territorial limit for the sale of the product, provision for the compensation of experts employed by the commission, which shall include a chemist, a bacteriologist, and a veterinary surgeon. It shall also control the location and character of the land employed for pasturage or for the cultivation of materials for fodder. It shall determine the construction, location, and drainage of buildings in so far as construction, location, or drainage may effect the health of the dairy stock, the removal of waste, or the character and conditions of the milk. It shall provide for an abundant and pure water supply, and prevent the use of water from shallow wells or springs holding surface drainage, or the use of any well or spring located within 300 feet of the stable. It shall include the protection of the stable and stock from a want of cleanliness and order; eliminate dirt, rubbish, and decayed animal or vegetable waste from the premises; and disallow the keeping of fowls, hogs, horses, or other live stock, except the cow, within 300 yards of the buildings used for dairy purposes. It shall regulate the health and breed of the animals, and exclude from the herd any animal that is judged by a competent observer to be tuberculous in any organ or part, or any animal with fever or disease proceeding from or associated with parturition, or found to be in a state of ill health prejudicial either to the herd or to the character of the milk, or any animal that was bred through close consanguinity within a period of three generations, or that was not kept sterile during the first twenty-seven months, or any phenomenal milker except that glandular disease or tubercle has first been excluded by a competent observer. It shall provide for the proper housing and care of the animals and their shelter from the influences of weather and climate detrimental to their health; their grooming and treatment; the prompt removal of waste products from the stable, and its freedom from animal odors by proper ventilation; the absence of conditions which would make the animal nervous, and prevent their use for milking purposes when in a state of excitement, either as a result of or during the period of estrus. It shall regulate the feeding, both as regards the materials which will determine the desired result in the product, as well as restrain the use of questionable or exhausted materials employed to increase the milking capacity, or that will result in impoverished milk. It shall govern the collection and handling of the milk, and insist upon a proper regard for cleanliness, as it is viewed from the standpoint of a physician and sanitarian and as it relates to the animal and her surroundings, the milker, the vessels, or to the association of persons handling the milk, with sources of infectious disease. It shall also govern, in minute requirements, every step in the cooling and preparation for shipment, and add to the product every known detail of care that will promote its keeping qualities and favor its safe transportation.

(3) That the commission shall carry on its work without pecuniary compensation. They shall endeavor to establish, from data gathered in clinical observations, correct standards of purity for cows' milk. They shall be responsible for a periodical and personal inspection of the dairy or dairies under their control. They shall provide for a bimonthly expert examination of the dairy stock by a competent and approved veterinarian, who shall be subject to a consulting and a supervising officer. The milk produced shall be subjected to chemical analysis and to bacteriological tests, made by experts under the direction of the commission, at such times as in its judgment is desirable, the cost of which shall be defrayed by the dairyman. The chemist, the bacteriologist, and the veterinary surgeon shall be selected by the commission; and when so requested, either periodically or otherwise, they shall

render their reports in writing. After receiving these reports the commission shall send a certified copy of the same to the owner or agents of the dairy under its supervision. This triple certificate, duly signed, shall constitute the product of the dairy "certified milk," provided it shall be sealed in separate quart containers marked "Certified milk," and bear the name of the producer, together with the date of milking. Being designed especially for clinical purposes, it should be subject to the following restrictions in its sale, namely, that when at any time the demand should exceed the supply, and the milk is required by a physician, either for infant feeding or the diet of the sick, the holder of a physician's order shall be regarded as a preferred purchaser. The reports of the experts, although designed for certificates, may also be used for the information of the medical profession in the localities where the milk is sold. Duplicate printed copies, bearing the signatures of the experts and the names of the commission, should be sent out at such times as may be agreed upon, and the circulation should, for obvious reasons, be limited to the physician.

### APUNTES SOBRE LA ALIMENTACIÓN EMPLEADA DURANTE LA PRIMERA INFANCIA EN LA ISLA DE CUBA.

Por el Dr. JOAQUIN L. DUEÑAS, Habana, Cuba.

Este trabajo, escrito con el objeto de satisfacer en lo posible los deseos manifestados por los Dres. Keating y Crandall, de los Estados Unidos, servirá para dar una idea general sobre el régimen alimenticio seguido durante la primera infancia en los niños de la Isla de Cuba. Una información rápida, practicada en diferentes localidades de la Isla, me ha permitido reunir datos de algún valor y complementar los conocimientos prácticamente adquiridos durante mi vida profesional en la Habana.

Desde un punto de vista general, puedo decir que la alimentación de los niños pequeños no está sujeta entre nosotros, sino con raras excepciones, á los sanos preceptos de la ley natural ó á los prudentes dictados de la ciencia. En cada provincia, en cada pueblo, en cada familia, existe un modo de criar distinto, impuesto por los hábitos heredados de varias generaciones. El destete lo realiza cada uno á su manera, casi siempre sin consultar la opinión del médico, sin cuidarse para nada de la trascendencia del acto que va á realizarse, ni de los peligros á que se expone la vida del niño, que atraviesa ese período crítico de su desarrollo, con más ó menos fortuna, según su resistencia individual.

En las poblaciones de alguna importancia, en la Habana, por ejemplo, se vé por todas partes el abandono hasta de los más elementales preceptos. Lo arbitrario es la línea de conducta que se sigue. En los campos no existen costumbres más sanas, y á cada paso tienen que luchar los médicos con los resabios de la ignorancia. Con objeto de contribuir á la desaparición de hábitos muy generalizados, cuyos efectos se reflejan en la estadística de mortalidad, publiqué el año pasado de 1892 una serie de artículos sobre el "destete" en *La Higiene*, periódico de vulgarización científica que dirige mi amigo el Dr. Delfin.

*Alimentación natural.*—La lactancia materna se emplea en toda la Isla, pero de distinto modo y con diferente resultado, según se considere en las capitales, en los pueblos de más ó menos importancia, ó en las viviendas rústicas.

En la Habana las condiciones del medio, densidad de población, calores excesivos, humedad, á las que se agregan otras muchas causas de orden biológico ó sociológico, contribuyen á debilitar la constitución de nuestras mujeres, y por lo tanto muchas de ellas no pueden resistir, sin peligro para la salud, las pérdidas que ocasiona una lactancia prolongada. Salvo relativas excepciones de señoras que tienen todo el vigor necesario para soportar una lactancia hasta los dos años del alumbramiento, la mayoría de las habaneras se resiente al cabo de cierto tiempo del gasto orgánico

empleado en beneficio de la criatura, viéndose precisada á acudir á la lactancia mixta artificial. Es muy general ver que los niños de pecho se mantengan con buenas apariencias de salud y lozanía á pesar de alguna decadencia de fuerzas en las madres, pero no es raro, por otra parte, observar en los niños la dispepsia por alteración cualitativa de la leche, la debilidad constitucional, la atrepsia. En tales casos lo más provechoso para ámbos organismos sería, ó la lactancia mixta femenina, en la que una nodriza mercenaria alterna en sus funciones con la madre, ó el cambio definitivo de nodriza, según lo exigieren las circunstancias. La lactancia mixta femenina no deja de emplearse algunas veces, pero las familias optan con más facilidad por la alimentación artificial por ser muy común la repulsión que se tiene á las nodrizas mercenarias, la mayor parte de la raza de color, dadas las pésimas condiciones en que se encuentra el servicio doméstico á consecuencia de tantos factores sociológicos como han contribuido fatalmente á su desorganización. Si á las deficiencias morales del servicio se agrega el elevado precio (\$30 á \$85) que exigen las nodrizas en la ciudad, se acabará de comprender porqué casi siempre se prefiere la lactancia mixta artificial. Esta determinación se realiza frecuentemente del quinto al noveno mes de la vida del niño, algunas veces antes, pero deja probada invariablemente la virtuosa disposición de la mujer cubana á amamantar sus hijos, á pesar de no permitírsele en muchas ocasiones la pobreza constitucional de su organismo.

En cuanto á las condiciones orgánicas de las nodrizas mercenarias, debo agregar que las mejores son las de raza negra; poseen una leche más rica, más nutritiva y soportan varias crías consecutivas, sin resentirse apenas en su salud. También son buenas las nodrizas de Canarias y las peninsulares, en su mayoría gallegas, cuando traen sus hijos; pero la regla general es que emigren dejándolos en su país y exponiéndose á perder considerablemente la secreción lactea después de una larga y penosa traversía.

En la Casa de Maternidad se emplea la lactancia natural como alimentación exclusiva de los niños de pecho. Los siguientes datos me han sido suministrados por mis distinguidos amigos, el Sr. Coppinger, celoso director del establecimiento, y el Dr. Montalvo, médico de la Maternidad. Cada niño tiene su nodriza destinada á cuidarlo y atenderlo á la vez que amamantarlo. Se le abonan \$30 mensuales, sufragándole los gastos accesorios de lavado de ropa, alimentación, confeccionada en una cocina especial, alimentos especiales, chocolate, etc., lo que hace aumentar el presupuesto para cada una á \$47 mensuales. Para saber lo que cuesta el sostenimiento de esa sección, basta saber que anualmente ingresan de 27 á 28 niños por el turno destinado á recibirlos. El destete se realiza gradualmente bajo la directa inspección del Dr. Montalvo, y se da el caso de ver niños de cerca de dos años que ya toman otros alimentos y todavía tienen una nodriza que les brinda maternalmente el pecho á ciertas horas.

En el interior de la Isla se emplea generalmente la lactancia materna para alimentar á los niñitos, pudiendo asegurarse que casi todas las madres dan exclusivamente el pecho á sus hijos durante los tres ó cuatro primeros meses de la vida y luego alternativamente con otros alimentos hasta una edad avanzada (dos años). El modo de administrarlo no está sujeto á otra regla que al capricho ó los hábitos de cada familia, siendo muy frecuente causa de trastornos intestinales la costumbre de amamantar con exceso al niño, ya durante el día, ya en las horas de la noche.

*Alimentación artificial.*—En la Habana se practica el destete prematuramente, pero por lo común de un modo gradual. La época que se escoge para empezarlo es la que transcurre del cuarto ó quinto mes al noveno, ya bajo pretexto de nuevo embarazo ó porque la madre cree debilitarse sosteniendo el niño á pecho solo. En muchos casos el empleo de la alimentación artificial obedece al deseo de fortalecer y engordar niños que no lo necesitan, que viven saludables y se hallan en buenas carnes, logrando con esto volverlos dispépticos y delicados ó enfermarlos gravemente. Esa es una tendencia bastante generalizada en nuestro país.

El alimento á que se dá la preferencia por su abundancia y baratez es la leche de vaca. Casi siempre se la administra hervida, en la proporción de dos partes de leche por una de agua, esto es, terciada, asociándole agua de cal ó de Vichy, bicarbonato de sosa, anís, cebada, té, con objeto de prevenir los trastornos que su digestión pudiera ocasionar. Sin embargo todas esas precauciones son inútiles para conjurar los peligros que resultan de las alteraciones que sufre la leche ya por la mala calidad de los pastos al entrar la primavera, ya por las múltiples causas de que he hablado en mi trabajo sobre las entero-colitis. En el empleo de la lactancia mixta artificial se cometen las mismas faltas que en la lactación materna. Es raro que se sujete al niño á un verdadero régimen basado en una higiene alimenticia bien entendida. No hay técnica sino en los casos en que interviene para dirigirla el médico de la familia; por consiguiente la única precaución de asepsia que se toma es la consagrada tradicionalmente por el uso, de hervir la leche varias veces al día, sobre todo en los meses calurosos del verano.

Desde el año de 1890, en la misma época en que comenzó á hacerse uso de la leche esterilizada en el extranjero, los Dres. San Martín y Fors empezaron sus ensayos de esterilización por un procedimiento especial en el Laboratorio de la Crónica Médico-Quirúrgica, y utilizando poco tiempo después la leche de excelentes vaquerías situadas en el occidente de la Isla, proporcionaron al consumo en los mercados, una magnífica leche esterilizada al vapor bajo presión en el autoclave, á una temperatura de 115° á 120° C. Esta leche que se vende desde entónces á 10 centavos la media pinta, ofrecía una buena garantía para la salud, siendo acogida favorablemente por el público que llegó á consumir desde que se implantó la mejora, unas diez mil botellas mensuales. Leche buena, superior á todas las que se expenden en la Habana, y además aséptica, estaba llamada á influir poderosamente en la conservación de la salud infantil, si la técnica especial que requiere para su administración fuese escrupulosamente practicada por las familias. Desgraciadamente no da resultados seguros mas que en aquellos casos en que la cultura individual se halla dispuesta á comprender los trascendentales beneficios del progreso.

Recientemente el Dr. Delfin ha ideado un pequeño aparato cuyo uso empieza á generalizarse, y que tiene por objeto esterilizar la leche que ha de consumirse durante el día, por medio de un sencillo procedimiento puesto al alcance de las familias.

El uso de la leche de burra en la Habana está restringido á un número menor de niños, y puede decirse que solo se toma por prescripción facultativa. La leche no es generalmente de buena calidad por deficiencia en la conservación y sostenimiento del ganado, y su precio no está al alcance de todas las fortunas. La leche de chiva ó cabra es muy poco usada, lo mismo que la de yegua cuyo empleo es excepcional.

Los alimentos que se preparan en el país para ayudar el régimen lacteo ó para sustituirle por completo, cuando el destete es definitivo, consisten en atoles ó papillas que se confeccionan con diversas harinas á las cuales se adiciona caldo más ó menos desgrasado, ó leche y azúcar. Este es el modo más común de comenzar la alimentación. La harina de trigo, de sagú, la maicena, la tapioca, la galleta pulverizada, la bananina ó harina de plátano, son las sustancias de uso más frecuente. También se emplean las *migas*, que se hacen con pan mojado en agua ó leche y un poco de sal, echando el todo en manteca hirviendo con ajos, hasta obtener una pasta de cierta consistencia que los niños toman con agrado. Las sopas de pan, las de leche, á la que se agrega azúcar y canela, las sopas de fideos ó tapioca, las patatas, el arroz con leche, son los primeros y más usuales alimentos, dejándose para más adelante los huevos, ciertas viandas, el pescado, ave ó carne.

Aunque este es el modo habitual de comenzar la alimentación de los niños en las familias habaneras, se dan casos no raros de trasgresiones higiénicas que consisten en hacer ingerir prematuramente sustancias de difícil digestión, incompatibles con el estado de desarrollo de los órganos digestivos. Legumbres diversas, frijoles y

judías principalmente, guisos variados como el de maiz, que los niños no mastican bien, quesos, dulces y golosinas de todas clases, que suelen producir gravísimas indigestiones y enteritis consecutivas.

Los alimentos artificiales que se importan del extranjero pueden ser colocados, según el diverso consumo que de ellos se hace, en el orden siguiente, teniendo en cuenta los datos que he recogido en diversas droguerías importadoras de la ciudad: leche condensada americana y suiza, harina lacteada de Nestlé, fosfatina Fallieres, alimento de Wagner, de Mellin, de Savory y Moare, harina malteada Defresne, grano imperial. De todos ellos se hace un uso variado como alimento supletorio ó adicional, ateniéndose á las indicaciones expresadas en los prospectos para su modo de administración y dosis. El que más se emplea es la leche condensada americana y muchas veces como alimento exclusivo, manteniéndose los niños en regulares condiciones de salud. Su poder nutritivo está subordinado en gran parte á la constitución del niño que lo toma. Los niños fuertes que no necesitan de rica y abundante alimentación para reparar sus pérdidas y desarrollarse, se encuentran bien con su uso, pero en la mayoría de los niños habaneros que utilizan la leche condensada de un modo exclusivo, la nutrición se hace con languidez, los colores son pálidos, las carnes blandas, revelan en suma, los atributos del linfatismo y de la anemia. La leche condensada representa, sin embargo, un papel importantísimo en la higiene terapéutica de ciertas dispepsias y enteritis. Cuando no hay el recurso de una buena nodriza y las demás leches no se toleran bien, constituye un alimento precioso para modificar con rapidez el aspecto de las deposiciones.

En el resto de la Isla la alimentación artificial varía según se la considere en las poblaciones de más ó menos importancia, ó en los pueblos pequeños, caserios, haciendas de labranza, sitios, etc. En las capitales de provincia, según los informes que acabo de recibir de varios compañeros, se observan costumbres análogas á las de la Habana. La leche de vaca es generalmente la base de la alimentación de los niños y suele adulterarse en los puntos en que escasea, con agua, leche de boniato ó grasas. En algunos lugares, como en Matanzas, en que no hay leche buena y abundante por haberse convertido muchas haciendas y potreros en colonias para la explotación de la caña de azúcar, ha subido el consumo de la leche condensada americana, el cual aumenta todavía en la estación de la seca á causa de la muerte de muchas reses y por deficiencia de la secreción en las restantes. En algunas provincias en que existen numerosas vaquerías, predomina el empleo de la leche de vaca, porque existe en Cuba la costumbre de repartir el ganado entre los vecinos ó sitieros con el objeto de conservarlo en el tiempo de la seca. Así cada familia puede disfrutar por cierto tiempo de la leche que le produce la vaca que se le entrega, pero desde hace poco los potrereros tienden á restringir dicho reparto en muchos lugares porque las vacas contraen el hábito de destruir las cercas que separan las fincas colindantes enseñando á rompedoras á las otras.

De todos modos, es costumbre muy seguida en los campos dar á los niños, que carecen del pecho de la madre leche de vaca, que se administra casi siempre hervida, pero las más de las veces pura y desordenadamente. También está muy generalizado el empleo de la chiva criandera, concordando en todos sus detalles, los numerosos informes recibidos de toda la Isla respecto al modo que se tiene de aprovechar este animal para la lactancia. Se habitúa al niño á practicar la succión directamente y al cabo de poco tiempo la cabra aprende y ejerce sus funciones como una verdadera nodriza, acudiendo solícita al llamamiento de la criatura y acomodándose de la mejor manera posible para facilitar al niño la succión. La cabra se aprovecha en toda la Isla, pero muy particularmente en todo el Occidente, provincia de Pinar del Rio y en algunas comarcas del centro y el Oriente.

En ciertas localidades de la provincia de Santiago de Cuba, en las haciendas de Bayamo y Tiguauí, en que existen grandes vaquerías, se aprovecha para alimentar á los niños el suero obtenido por expresión de la leche, coagulada por medio del cuajo, para la elaboración del queso.

Respecto á la leche de burra y la de yegua, se usan con rareza, cuando el facultativo la prescribe ó el niño no digiere bien alguna de las leches anteriores.

Hay un hecho que debe fijar mucho la atención y que por sí solo basta para juzgar del pésimo estado en que se encuentra la alimentación de la niñez en toda la Isla. Lo defectuoso del régimen consiste en no someter exclusivamente á leche á los niños. El acuerdo, en la opinión de todos los médicos que me han escrito, es unánime. Ya disfruten del seno materno en toda su abundancia, ya de una lactancia mixta más ó menos impropia, lo frecuente es que desde el tercero ó cuarto mes, bajo pretexto de que se crían débiles á leche sola, se les pone en la boca primero el pedazo de pan, luego el boniato salcochado, el plátano verde frito ó asado, é insensiblemente se vá desde la sopa de pan ó de fideos á la de arroz, *casabe*, carne ó tasajo para que lo *chupe*, concluyéndose por saber que el niño, sin haber terminado el período dentario, come ya de todo como los mayores de la casa.

Las papillas que se usan al comienzo del destete, entre los campesinos razonables, se preparan lo mismo que he dicho antes, con caldo ó leche, á los cuales se agrega harina de trigo, de sagú cosechado en el país, ó maicena (fécula de maíz). La harina de maíz también se emplea muchísimo, pulverizando el maíz en un molino de piedra cuyo diseño adjunto.

Se echa el maíz por el ancho orificio situado en el centro del disco superior, y por medio de un movimiento giratorio impreso al mango de madera, se tritura el grano entre las dos piedras, las cuales van dejando escapar poco á poco las partículas por el intersticio que las separa. El producto así obtenido se llama rollón y con él se prepara la papilla, agregándole leche hervida y un poco de azúcar.

Con el plátano verde frito, machacado en un mortero, se fabrica también una harina que sirve para hacer papillas, cuyo empleo es general en toda la Isla. Dotada de alguna consistencia ya sólo ó unida á otros alimentos, se deposita en la boca del niño después de haber amasado cierta cantidad entre los dedos. Este procedimiento del bocado tiende á sustituir en muchos puntos del campo al antiguo proceder del mascado, que consiste en introducir en la boca del niño el alimento previamente masticado ó insalivado por otra persona. El alimento empleado por algunas familias campesinas bajo esta repugnante forma, es el plátano verde frito, transversalmente cortado en angostos discos, ya sólo ó mezclado con pequeños pedazos de carne de puerco ó chicharrón, que no es otra cosa sino la piel del puerco unida á cierta cantidad del tejido celulo-grasoso que la sustenta y que se fríe y achicharra al fuego. También se asocia la carne de puerco al boniato ó al plátano maduro, constituyendo un alimento muy agradable al paladar.

El proceder de la tetera está asimismo muy generalizado. Consiste en colocar un pedazo de pan, de galleta, de panetela ó cidra dentro de un pequeño trapo, sujetándolo después con un hilo, á la manera que se dispone la gasa para el tapónamiento intracervical del útero. Hecha la tetera se sumerge en un poco de agua, sola ó con vino ó leche, y se da á chupar al niño, remojándola las veces que sean necesarias.

De los alimentos importados, la leche condensada americana y la harina lactea de Nestlé, son los que únicamente se emplean, siempre en mayor proporción en las capitales de provincia ó en las poblaciones de cierta importancia, que en los pueblos,

caseríos, colonias ú otros conglomerados humanos, donde puede calificarse de insignificante ó nulo el consumo que de ellos se practica.

Sería prolijo insistir ahora en los resultados de tantas trasgresiones higiénicas como se cometen al alimentar viciosamente á los niños, del mismo modo que al sujetarlos á la ingestión de aguas de pozo ó manantiales sin filtrar ni hervir. La dispepsia, la dilatación del estómago, las enteritis, los vermes, la eczema, son las enfermedades más comunes en los campos y en los poblados del interior. Los bebés de vientre grueso se ven por todas partes. Las infecciones de todo género por el tubo intestinal, encuentran un terreno preparado de antemano para realizar con más facilidad sus terribles estragos.

En resumen: en la Isla de Cuba la alimentación de los niños de la primera infancia no está sujeta á los preceptos higiénicos sino en las poblaciones de cierta importancia y entre las familias de cierta cultura intelectual.

El modo más frecuente de alimentar á los niños es por medio de la lactancia materna durante los primeros meses de la vida. De un modo general puede decirse que son buenas las condiciones de la mujer cubana para el amamantamiento de sus hijos, siendo menos numerosas las buenas nodrizas en las ciudades y debilitándose más pronto que las campesinas.

La tendencia de nuestras madres en toda la Isla es destetar prematuramente á sus hijos sujetándolos, en las poblaciones, á la lactancia mixta artificial; en los campos á una alimentación viciosa, pero sin dejar de darles el pecho á veces hasta los dos años ó más.

La leche á que se dá la preferencia de ordinario es la de vaca por su abundancia y baratez (5 centavos la pinta); en segundo lugar, la de burra en la Habana ú otras poblaciones importantes; la de chiva en los campos, usándose en último lugar la de yegua. La leche esterilizada no se consume más que en algunas capitales de provincia, sobre todo en la Habana y alrededores.

La leche condensada americana y suiza, pero sobre todo la primera, son de uso muy general en ellas, desconociéndose su empleo casi en absoluto entre los campesinos ó guajiros.

Los demás alimentos artificiales que se importan del extranjero son escasamente administrados aún en las capitales, á excepción de la harina láctea de Nestlé.

La primera alimentación, confeccionada por el arte culinario en las ciudades, consiste en el empleo de papillas ó atoles de sagú ó trigo con caldo ó leche, las migas, bananina, sopas ligeras de pan y luego de fideos, tapioca ó revalenta. En los pueblos de campo se usan las mismas papillas de sagú ó de trigo, pero sobre todo las de harina de maiz y las de plátano verde. Se anticipa el empleo de otros feculentos, como el boniato, las patatas, la malanga, el arroz, etc.

La alimentación viciosa consiste en el uso más frecuente en los campos, pero limitado en las ciudades á las familias de poca cultura intelectual, de sustancias inadecuadas á la edad y desarrollo del niño: ciertos feculentos, como el ñame, la yuca; leguminosas como frijoles, judías, frutos diferentes, algunas veces verdes, dulces de todas clases, helados, quesos y productos más complejos del arte culinario.

No debo levantar la pluma sin dejar consignada mi más profunda gratitud á los dignos compañeros que han querido favorecerme con sus instructivos informes. Los primeros ejercen su profesión en las distintas localidades de la Isla que se expresan; los segundos, residentes en la Habana, han permanecido más ó menos tiempo en el campo:

## A CONTRIBUTION TO THE STUDY OF PRIMARY ENTERO-COLITIS IN EARLY INFANCY.

By J. L. DUENAS, M. D., of Havana, Cuba.

In Havana, as in all populous cities of either hemisphere, the proportion of cases of and deaths occasioned by intestinal diseases among infants reaches a very high figure. Besides simple diarrhœa and Hayem's green diarrhœa, many cases of acute entero-colitis occur of greater or less intensity, which are either cured by an appropriate treatment or pass into a chronic state, attended sometimes with secondary ailments, which are but the consequence of neglected intestinal troubles.

In order to have an idea of the damages caused by enteritis among the children of Havana it is only necessary to direct one moment's attention to the demographic charts so scrupulously figured out by Drs. Delfin and Laguardia since 1890. Thus, the mortality from enteritis in that year (1890) included 417 children under 2 years of age, equivalent to 5.71 per cent of the total of deaths (7,298) in the entire population. In 1891, out of a total of 7,030 deaths, 1,556 were children under 2 years of age, 566 of them (36.37 per cent) having died of diarrhœa. In 1892 a total of 6,963 deaths were registered, 1,535 of which belonged to early children, 399 (26.99 per cent) having been occasioned by diarrhœa, so that each year between 400 and 550 little children are carried off in this city by acute diarrhœa, equivalent to a maximum of 2.75 deaths per 1,000 inhabitants. If the above figures be compared with those given by Dr. Smith concerning the city of New York during the year 1892 a marked difference will be observed against the Havana mortality, for in New York the mortality among children under 5 years of age only represented 2.90 per 1,000 inhabitants, from which it must be inferred that for children under 2 years of age the mortality would have given a figure much lower than ours. Such results are most harassing in a city which barely contains 200,000 inhabitants, and where the proportion of births to deaths presents an alarming balance against the population. The important factor that we are considering well deserves, therefore, to be taken into account in order to lessen as much as possible its fatal influence.

The observations which I shall present concerning the intestinal troubles of early infancy refer exclusively to the acute primary entero-colitis. No account will be taken of catarrhal diarrhœas or simple diarrhœa, such as rapidly disappear under the use of simple remedies, nor shall I include in my statistics all the cases observed by me in the course of my thirteen years' practice, but only those that I have attended in 1891 and 1892, all of which have been carefully examined and analyzed with the aid of previous experience acquired in the observation of infantile diseases. Before proceeding any farther I must observe that, not occupying any official post in the public institutions where sick children are admitted, the corroboration of pathological anatomy will be wanting in my observations, owing to the insurmountable difficulties in the way of obtaining autopsies in private practice. This paper must therefore be understood to be written only from an etiological, clinical, and therapeutic point of view.

My cases from a total of 155 children attended with acute primary enteritis during the period of first dentition. They are distributed as follows: Boys, 93; girls, 62; total, 155. Brought up entirely or partially on the bottle, 114; brought up entirely on mother's milk, 41; total, 155. Twenty-five of the former (21.93 per cent) and 3 of the latter (7.32 per cent) died. Total of deaths, 28, equivalent to 18.05 per cent. The same cases, classified according to the age at which the disease was contracted, give the following order:

| Age.               | Cases. | Deaths. | Mortality.       |
|--------------------|--------|---------|------------------|
|                    |        |         | <i>Per cent.</i> |
| 1 month.....       | 11     | 1       | 25               |
| 2 months.....      | 11     | 3       |                  |
| 3 months.....      | 16     | 4       |                  |
| 4 months.....      | 15     | 5       |                  |
| 5 months.....      | 11     | 4       |                  |
| 6 months.....      | 11     | 2       | 9                |
| 7 months.....      | 6      | 1       |                  |
| 8 months.....      | 7      | 2       |                  |
| 9 months.....      | 11     | 0       |                  |
| 10 months.....     | 6      | 0       |                  |
| 11 months.....     | 4      | 0       | 13.51            |
| 12 months.....     | 9      | 1       |                  |
| Second year *..... | 37     | 5       |                  |
| Total .....        | 155    | 28      | .....            |

\* Almost all the cases here included in a single group occurred between the twelfth and fifteenth months.

The 155 cases distributed according to the months in which they occurred appear in the following order:

|               |    |                |     |
|---------------|----|----------------|-----|
| January.....  | 13 | August.....    | 16  |
| February..... | 15 | September..... | 4   |
| March.....    | 16 | October.....   | 5   |
| April.....    | 15 | November.....  | 13  |
| May.....      | 11 | December.....  | 10  |
| June.....     | 21 |                |     |
| July.....     | 16 | Total.....     | 155 |

Classified according to the form of the disease, they consisted of—

|                              | Cases. | Mortality.       |
|------------------------------|--------|------------------|
|                              |        | <i>Per cent.</i> |
| Types:                       | 12     | 66               |

*Etiology and nature of the disease.*—The following causes are reckoned among those that most commonly bring about the acute infantile enteritis in Havana: (1) Exposure to cold; (2) premature weaning; (3) indiscriminate use of cow's milk in the feeding of infants; (4) the use of food not adapted to the child's age; (5) the effect of high temperatures during the summer months, which is also our rainy season; (6) various infectious influences which habitually prevail in this locality. These various etiological conditions generally combine in many ways to produce the intestinal troubles. Most of them, however, only deserve to be considered as occasional factors, modern investigations having conclusively demonstrated the important rôle that belongs to infection as the primordial pathogenic agent in these diseases.

(1) Children are quite as liable to catch cold among us as they are in cold climates. The special construction of our houses, the constant breeze which prevails during the hot season, the common habit of opening doors and windows to mitigate the oppressive heat, the sudden fall of temperature after heavy showers, are frequent occasions of catching cold for the children of this country, generally very lightly

dressed, especially when suddenly exposed to drafts after awaking from their sleep, or after taking their milk, which frequently provokes perspiration.

(2) Premature weaning must also be considered as one of the predisposing causes of enteritis. The bad conditions of many of our wet nurses, their ignorance or low social grade, etc., induce many mothers to wean their children prematurely, thereby exposing them to the dangers of the following etiological agencies:

(3) The expenditure of cow's milk to the public is carried on under the most deplorable conditions for the feeding of infants. The rules of sanitary police are utterly disregarded. The cows, mostly attenuated or diseased, insufficiently fed, or supplied with a bad quality of pasturage, are led through the streets of Havana, frequently lying down, so that their udders come in contact with a soil infected to the highest degree with organic detritus of all kinds. The consequence is that even when milked before the very eyes of the consumer the milk is liable to be contaminated with pathogenic germs, putting aside the readiness of the milkman to adulterate the article by the addition of large quantities of water, in which Dr. Davalos has bacteriologically demonstrated the presence of various microbes, and in particular of the bacillus coli communis, so well known for its pathogenic properties. As to the milk which is sold in coffee-houses, milk depots, etc., it is often brought from considerable distances, and consequently delivered many hours after it has been milked. It is conveyed in tin cans so constructed that they can not be thoroughly cleansed, being greatly shaken before reaching its destination, and, moreover, adulterated, to say the least, with impure water, such as until the present year has been drunk in this city. All the above circumstances combine to produce the fermentations so well studied among us by Dr. Delfin, author of several important papers on that subject. In one of them\* our colleague has called attention to the frequency and death rate of cholera infantum and to the fermentations developed in the milk under the influence of our high summer temperatures. If in addition to all these circumstances we take into account the carelessness with which artificial lactation is carried on in the households of Havana, the importance of this factor in the development of infantile diarrhœa will be readily understood.

Many of my colleagues have come to identical conclusions. Drs. Madan and Garcia Rijo,† in particular, have carefully studied the etiological influence just pointed out.

The best testimony that I can adduce to prove the dangers of lactation carried out under such unfavorable conditions is the fact that in the course of my thirteen years' practice I have only met with a comparatively small number of cases of enteritis among children exclusively fed from mother's milk, and such cases as did occur have afforded a more favorable termination (a mortality between 5 and 7 per cent).

(4) The use of improper food, of indigestible substances, of sweetmeats made with milk, cheese, ice cream, fruit, and other delicacies too early granted to children, have been in many of the cases observed by me the occasioned cause either of severe enteritis or of the clinical syndroms known as "cholera infantum."

(5) The injurious influence of heat is very remarkable in Havana, and has long since been pointed out. Even in the cooler season from December to March, when the average temperature ranges between 64° and 68°, there are days when the thermometer rises as high as 82° or 86°, and the enteritis is again observed. In mid-summer the temperature rises as high as 90°, 93°, and 97°, the number of intestinal disorders increasing with the intensity of the heat, as shown in the tables of comparative mortality for the period 1888-1892, given further on.

† Garcia Rijo. Apuntes clinicos sobre el envenenamiento por la leche en los recién-nacidos y fiebres de la infancia (Primer Congreso Medico Regional, p. 212. Habana, 1890). Madan. Consideraciones sobre las diarreas graves de la primera infancia (Cron. Med. Quirung.) Tomo i 6, p. 476 y 545. Habana, 1890.

The 155 cases noted down in my own case book for the two years of 1891 and 1892 present the following monthly distribution:

|                |    |                 |    |
|----------------|----|-----------------|----|
| January .....  | 13 | July .....      | 16 |
| February ..... | 15 | August .....    | 16 |
| March .....    | 16 | September ..... | 4  |
| April .....    | 15 | October .....   | 5  |
| May .....      | 11 | November .....  | 13 |
| June .....     | 21 | December .....  | 10 |

The highest morbidity corresponds to the months of June, July, and August, and it is particularly to be noticed that in the months of March and November, which are frequently warm, a corresponding increase occurs in the number of cases, a fact also observed in the general demographic statistics for the years mentioned above. Inasmuch as the summer heat by itself can not be regarded as capable of producing the diarrhœa, I shall consider in the next paragraph what seems a plausible explanation of the anomalies offered by the curve of morbidity and mortality.

(6) Three infectious diseases, which prevail endemically or epidemically in Havana, deserve to be particularly considered, owing to their primary localizations in the intestinal tract. They are typhoid fever, paludism, and grippe. There is besides, a numerous group of fevers, not yet etiologically classified, which may for the present be included, so far as their clinical features are concerned, among the typhoid fevers. They constitute toxi-infections originated in the intestinal tract, bearing great resemblance to the incomplete forms of typhoid fever, their duration being more or less prolonged and likely to be modified by the appropriate employment of purgatives and intestinal antiseptics in their treatment. The etiological conditions that preside over the development of all these fevers are to be sought partly in the composition of the soil, in the quality of our water supply, such as it has been until last year, and also in the well-known disregard of everything appertaining to public hygiene. The collection of garbage is very deficient; the streets are badly paved, and in main wards not properly swept, whereby infectious foci of every kind are formed all over the city during the rainy season. The sewerage is as bad as can be; it is not carried out on a general system, but only consists of very poor drains, deficient in size, declivity, and workmanship, and scarcely calculated to prevent the filtration or accumulation of corrupt matter in the soil of the city. In addition to this a most defective system of cesspools is used in our houses, and the municipal ordinances are often infringed, the privies being surreptitiously connected with the sewers which run along our streets. From this it will be readily understood that the muddy soil of Havana, lying as it does upon an impermeable subsoil, must be completely saturated with infection. According to the calculations of our engineers, Messrs. Gonzalez and Amigó, every year 79,200,000 kilograms of fecal matters find their way into the soil around the cesspools and sewers. It is no wonder, therefore, that in a dense city like ours, where all the etiological elements favorable to organic decomposition are present, heat and moisture in particular, the air should be greatly contaminated with impurities, and charged with deleterious effluvia and microbes which being deposited on the walls of the pharynx, are afterwards swallowed with the food and drink, thereby producing many kinds of infection in the intestinal canal. All that Dr. Lewis Smith has written in his book on Diseases of Infancy regarding the causes of enteritis is verified in Havana upon an enlarged scale, and if the results have not been worse it is undoubtedly due to the influence of the winds which constantly purify our atmosphere, and to the copious rains that wash out our imperfect sewers.

The etiological conditions already described affect all the inhabitants of the city, but as will be readily understood, their influence is more disastrous upon infants, principally upon those that are badly lodged and improperly fed. In more advanced childhood, in youths, and even in adults, the infection is apt to assume another

----- Deaths from typhoid fever at all ages during the year 1888.

———— Deaths from enteritis at all ages during the same year.

The statistics for that year do not give the deaths rate according to ages, so that no distinction can be made between adults and infants.

----- Deaths from typhoid fever at all ages during the year 1889.  
 ————— Deaths from enteritis at all ages during the same year.

The statistic for that year do not give the deaths rate according to ages, so that no distinction can be made between adults and infants.

----- Deaths from typhoid fever at all ages during the year 1890.

———— Deaths from enterocolitis in infants during the same year.

----- Deaths from typhoid fever at all ages during the year 1891.

———— Deaths from entero-colitis in infants during the same year.

In this chart a relation between the two curves apparent. The cases of typhoid fever were milder and less numerous than usual.

6. Enteritis in a girl 15 months old.

7. Intestinal infection in a girl 4 years old.

8. Relapsing enteritis in a boy 5 months old.

9. Gastro-intestinal fever in a boy 6 years old.

10. Enteritis in a girl 4 months old.

11. Intestinal infection in a girl 14 years old.

clinical character, so that the prevalence of infantile enteritis often coincides with the intestinal fevers already spoken of, and with cases of regular typhoid, all of which pathological conditions obtain a common source of development in the multiple factors already mentioned. In support of this assertion I need only call attention to the relation between the monthly mortality from entero-colitis of infancy and that from typhoid fever during the years 1888-1892. The agreement between the two curves would be still greater if all our physicians adopted an identical criterion. Notwithstanding the discrepancies regarding the classification of diseases, the parallelism between the mortality curves of those infections is sufficiently apparent, but it is even more so from a clinical point of view when we consider the distribution of both diseases in wards, presenting similar hygienic conditions (Figs. 1, 2, 3, 4, 5, 5 bis.)

It will be readily seen that in the years in which typhoid fever prevailed the cases of entero-colitis were more frequent and more severe. The month of June has nearly always presented the highest mortality; the latter varies in different years during the months of July, August, and September, decreasing considerably in this last month. To the months of March and November corresponds sometimes an increase in the number of cases and deaths, which may be attributed to several conditions either of a general or local character, among which may be mentioned, besides the atmospheric temperature, the prolonged dryness of the first months of the year; the retention of faecal matter in the sewers; the defective construction of some dwellings; perhaps also the greater virulence acquired by the pathogenic germs in some districts, and the propagation of morbid foci through which a revival of the infection is effected.

Let us now compare these two series of tracings, the first corresponding to entero-colitis free from choleriform symptoms, the second to fevers such as have already been spoken of in older subjects. A remarkable similarity will be observed in the temperature curves of both series, so much so that when other characters common to both morbid conditions are considered with respect to their symptomatology, course, and prognosis one is inclined to believe that they belong to the same class of diseases (Figs. 6, 7, 8, 9, 10, 11, 12, 13).

The bacteriological investigations to which the faecal matters proceeding from my little patients have been submitted were accomplished by my learned friend, Dr. Dávalos, at the Laboratorio de la Crónica Médico Quirúrgica. His exhaustive work confirms once more the results obtained in similar cases by other bacteriologists in different countries—such as Emmett Holt, Escherich, Baginsky, Lesage, and Macaigne. In all my cases Dr. Dávalos has found bacteria of different species; the habitual saprophytes of the intestinal canal, the *bacillus subtilis*, the *B. termo*, *staphylococcus pyogenes aureus*, but principally the *bacillus coli comunis*, which, through its soluble products, determines the secondary phenomena of toxi-infection when they are not transformed in the liver and favorably eliminated through the renal filter. (Gilbert.)

Besides these infectious causes, which are the most prevalent and have been more particularly studied, paludism and gripe are sufficiently common in Havana to provoke in small children cases of acute primary enteritis, with symptoms that can not always be differentiated from those of the other species previously mentioned. In such cases an etiological diagnosis can only be obtained by inquiring deeply into every particular and calling to our aid all the resources of general and clinical observation. It is, then, necessary to study the media and other conditions surrounding the sick. The malarial enteritis generally coincides with the appearance of correctly diagnosed malarial fevers. It is found to occupy the same foci, and may be differentiated by a thorough etiological inquiry, by a proper examination of the blood, by the organic lesions which malaria leaves behind, by its tendency to reappear under one or other of its forms, or by the readiness with which its various manifestations subside under the use of quinine. In doubtful cases it is necessary to be very cau-

tious in the etiological diagnosis and in the employment of medicines founded thereon, for errors, one way or the other, may have fatal consequences for the little patient.

The grippe enteritis coincides with the endemic grippe and recurs with the latter in certain seasons of the year. It is generally observed in families where other of the many clinical forms of grippe are simultaneously developed, or as instances of subsequent propagation; and, excepting some special cases, its true nature can almost always be correctly established.

*Clinical considerations.*—All my cases can be grouped under the two headings:

|                           | Cases. | Mortality.       |
|---------------------------|--------|------------------|
|                           |        | <i>Per cent.</i> |
| Cholera infantum.....     | 12     | 66               |
| Acute entero-colitis..... | 143    | 13.99            |
| Total.....                | 155    | .....            |

I shall only discuss the second group, which, besides being more frequent, offers greater clinical varieties, and is more open to doubt where etiology, diagnosis, prognosis, and treatment are concerned. Cholera infantum, on the other hand, is more regular in its manifestations and its treatment, though often unsuccessful, is less subject to discussion.

The more frequent forms of infantile entero-colitis observed in Havana are the common form described by authors, the thoracic and the cerebral; the gastric, remittent, dysenteric, typhoid, and choleraic forms being also occasionally met with. The common form of the disease is generally preceded by intestinal disturbances, to which little importance is given. More rarely it breaks out suddenly, in which case the fever, which, as a rule, comes out at night, generally precedes the diarrhœa, and the course of the morbid process is not so much that of an enteritis as of an infection originating in the intestine. Whatever the beginning may have been, the cases may be classified in three groups: light, moderate, and severe. In the first group the abdominal symptoms are moderate and the general phenomena variable, but of mild intensity. I shall not insist on the number or characters of the evacuations, my principal object being to present a brief outline of the morbid process as a whole. The temperature ranges between 99.5° and 101.5° F., or little more, during the febrile stage, which lasts from two to five days. The intestines are somewhat more tardy in recovering their normal functions. Relapses are frequent. (See the adjoining charts, Figs. 14, 15, 16, 17, 18, 19.)

In the second group the symptoms are more marked, but not all in the same degree. Some of the general phenomena acquire greater intensity. Restlessness, excitement, insomnia, and moaning are observed. The tongue is coated; there is anorexia, thirst, nausea, and sometimes vomiting. The abdomen is more or less sensitive to the touch in the region of the small intestines or in that of the ascending and transverse colon. The character of the evacuations varies considerably. The fever is of a subcontinuous type during the first days, afterwards becoming remittent, and then gradually decreasing as the local phenomena subside. In other cases it is remittent from the beginning, and even intermittent, from which it must not be inferred that it is malarial, for all these types have been pointed out by observers who practiced in cities where malaria did not prevail. Recent investigations have, moreover, brought to light the pyretogenous properties developed by microbial toxines through the nervous system. Finally, it is not uncommon to observe a persistence of thermic oscillations after the evacuations have recovered their normal appearance, thereby showing the infectious character of the disease. Calomel and antiseptics rapidly control the thermic disturbance. If this be not attained, the etiological conditions must be further investigated and the resulting indications opportunely acted upon. The duration of these cases of moderate intensity varies between one and two

weeks, which may be prolonged in an apyretic condition over three or more weeks, subject in a great measure to the influence of the dietetic plan that has been adopted. (See the adjoining charts, Figs. 20, 21, 22, 23, 24, 25, 26, 27.)

In the group of severe cases the symptoms are either more alarming from the onset or else they become so during the course of one or other of the forms already described. The predominance of cerebral phenomena justified the different names given to these cases by some authors: eclamptic, convulsive, comatose, meningitic, or pseudo-meningitic. The intensity of these symptoms may be such as to carry off the little patient within a short time if he proves unable to withstand the infection; but they can often be checked provided opportune and energetic measures are at once taken. If so, the severe symptoms gradually subside and, other complications being prevented, the fever ceases and the child is soon restored to health. But this is not always the case. The infection may return with renewed force, and after an interval of comparative calm the dangerous symptoms break out again, attended with an elevation of the central temperature, with coldness of the extremities, and scanty urine. If the discharges have been abundant or the child is of feeble constitution, pseudo-meningitis makes its appearance, with its well-known symptoms. In either case a fatal termination often occurs in spite of all our efforts. In other cases the bowels become paretic, probably owing to sapræmia, as Dr. San Martin has suggested. The consequences of this pathological complication are fearful; purgatives, massage, cold enemata, are unequal to the task of rapidly emptying the intestines; the toxins formed high up in the bowels soon invade "en masse" the infant's delicate organism, and within a few hours of the attack the child dies with all the phenomena of rapid uræmia. The thermic cycle of all these cases deserves to be known. Hyperpyretic accessions of subirritant type, irregularities in the acme, simulating the course of pernicious malaria are observed, all of which will be readily understood by a glance over the adjoined charts, better indeed than from a verbal description (Figs. 28, 29, 30, 31, 32, 33, 34, 35, 36, 37).

Besides the symptoms properly appertaining to the enteritis, upon careful examination, and when there is but little tympanitis, a moderate amount of hepatic congestion may be discovered. In docile children the sharp edge of the liver may be felt by using the method of the nail, which occasions some degree of pain. I have found hepatic hyperæmia in many cases of acute enteritis, and I call attention to it, because it might be erroneously attributed to a malarial origin. Its occurrence need not surprise us if we remember that this organ attains its highest functional activity in early life and reckons among its attributes the elimination of the toxins elaborated by the intestinal microbes.

Regarding the gastric, choleraic, typhoid, and dysenteric forms, I have nothing to add to the complete descriptions of our text-books or to more recent contributions of renowned specialists, but shall merely present the adjoined temperature charts as obtained from my little patients (Figs. 38, 39, 40, 41, 42, 43, 44).

Before leaving the subject I shall describe some other types or varieties concerning which I possess complete notes.

The remittent type resembles the pyrexia of older children in its thermic cycle and in its duration, which fluctuates between two and four weeks. It is perhaps one of the clinical forms of *B. coli* infection which most demands to be distinguished from typhoid fever and from remittent malarial fever in accordance with the criterion presented in our chapter on etiology.

Finally, there is a very dangerous variety of infectious enteritis which surprises by its apparent benignity. After a few days of moderate diarrhœa of greenish color and fœtid smell, attended with emaciation and *malaise*, symptoms of gastric disturbance make their appearance, consisting of nausea, sometimes vomiting and spells of gastralgia, followed by intervals of relief, during which the expression of the face is somewhat apathetic. The abdomen is soft, depressible, and sensitive to pressure, no signs of visceral congestion are observed, the temperature continues normal at all hours, but there is persistent anuria. Suddenly the breathing becomes

irregular, the spell of gastric pain reappears, the face becomes livid, and the child dies quietly by asphyxia or after some slight convulsions in the extremities and with dilated pupils.

The thoracic form described by Sevestre and Lesage and subsequently by Gaston and Renard is pretty common in Havana, cases being observed of all grades of intensity from simple bronchitis to generalized broncho-pneumonia. When the course of the disease is prolonged and the child has a delicate constitution, tuberculosis may declare itself, as exemplified in Chart No. 45.

*Treatment.*—Leaving out cholera infantum, the treatment of acute enteritis must necessarily vary in each case according to its intensity, form, and nature; but the following principal indications must be borne in mind: (1) Relieve the intestinal canal of its contents; (2) procure an antiseptic condition and functional repose to the organ; (3) restore the wasted energy; (4) combat special symptoms and complications. Of course, whatever be the form of the disease, the essential point is to empty the bowels. The old purgative plan which was directed against one of the symptoms of enteritis has now a causal indication, through a better knowledge of the origin and pathogeny of the disease. Calomel, in doses of 5, 10, 20, 50 centigrams or more, according to cases, followed by castor oil, is the remedy that has given the best results. I am convinced that when the disease has followed an unfavorable course, notwithstanding its employment, it has been due to one of the following circumstances: Late intervention; persistent paresis of the intestine; extraordinary intensity of the infection. After obtaining the beneficial results of this antiseptic purgative, three indications have to be satisfied: To maintain the antiseptics of the intestines; to keep the organ in complete repose, and to restore the lost energies. Salol, salicylate of magnesia or bismuth, and benzo-naphthol are the agents that have given me more brilliant results, while hydric diet, which I have used since the beginning of my practice, realizes the two additional indications. The water should be boiled and given in small quantities at prudent intervals, either cool or iced, with or without the addition of rum or cognac. The duration of the hydric diet should not be continued beyond twenty-four or thirty-six hours as a maximum.

Other symptomatic or causal indications may be required to be attended to. So the employment of local emollients, of cold compresses, of cold, antiseptic enemata, of general baths, frictions, revulsives, massage, may be called for. The use of certain internal remedies, such as opium, alcohol, quinine, tonics, caffeine, acids, alkalines, etc., according to the form, period, nature, or complications of the disease, may contribute to improve the condition of the patient, for whom resources of all kinds may be needed before he can be restored to health. I have learned by experience that the persistence or aggravation of a symptom, or even the fatal termination of the disease, may depend on the omission or imperfect execution of some detail, on the doses and manner of administering some medicines, on the slightest negligence or forgetfulness in the attendance.

I consider the hygienic alimentation of capital importance in enteritis. The choice of a proper wet nurse is the best guarantee for his recovery. Failing this I give the preference to ass's milk, next to the condensed milk, and lastly to cow's milk (preferably sterilized). Whatever food be chosen, the technical precautions of lactation must be scrupulously observed, else the convalescence may be interrupted by relapses, which are always prejudicial to the child and not infrequently to the physician's reputation.

#### CONCLUSIONS.

(1) Clinical observations and demographic statistics show that infantile enterocolitis, in all its forms, occurs in Havana with a death rate as high as that observed in other populous cities.

(2) The two principal types observed are cholera infantum and enterocolitis proper.

45. Girl 3 months old. Hereditary tuberculosis. Milk diet from the bottle. Had presented during the tuberculous patient with

previous 15 days fetid diarrhea and broncho-pneumonia had declared itself. In the same house there was a numerous bacilli in the sputa.

(3) The majority of cases belong to the second type in one or other of its numerous forms.

(4) The promoting causes of entero-colitis in Havana are due (*a*) to the deplorable hygienic condition of the city, deficiencies in the public administration, infection of the soil, air, and water; (*b*) to the indiscriminate employment of cow's milk or of other articles of food not suited to the child's age.

(5) Other causes, such as exposure to cold, summer heat, the use of the feeding bottle, the process of dentition, constitutional weakness, etc., render the infant's organism more susceptible or promote the pathogenous action of the infectious agent.

(6) From an etiological point of view the cases may be classed in three principal groups: (*a*) Intoxications through the ptomaines contained in the milk or other food administered to infants; (*b*) toxi-infections occasioned by saprophytes (intestinal septicæmia of Bouchard), such as Hayem's bacillus or the bacillus coli communis, which are apt to become pathogenous under certain biological conditions; (*c*) Specific infections having a tendency to become primarily localized in the intestines, such as result from malaria or from influenza.

(7) The pathological process consists in intestinal symptoms more or less marked, and of infectious origin, sometimes latent, and in secondary phenomena due to a general auto intoxication in which different organs may be involved in variable degrees, the kidneys being constantly affected.

(8) The extension and severity of the disorders are subordinate on the one hand to the nature, abundance, and virulence of the morbid agent, and on the other to the individual conditions of the patient. Hence it may be readily conceived that an insensible gradation must exist, from the mildest cases of apyretic diarrhœa to the most characteristic and most violent forms.

(9) The clinical phenomena presented by the patient do not always bear a constant relation to the nature of the infectious agent. In other words, the specific form of the disease does not depend on the specific nature of the etiological or microbic agent. Thus a given infectious agent, the bacillus coli communis, for instance, may occasion a simple diarrhœa, an enterocolitis of inflammatory type, or the clinical phenomena of cholera infantum; and inversely, the chemical and biological alterations in milk, the saprophytic germs, the bacillus coli communis, Hayem's microbe, or malaria are capable of producing local and general disorders similar in form, duration, and intensity to those of the morbid process under consideration.

(10) The clinical diagnosis, therefore, can only be said to correspond to a particular etiological origin after this has been proved through a series of minute and extensive inquiries, for which clinical sagacity, laboratory investigations, and pathological anatomy must be called in aid before scientific accuracy can be attained, otherwise the specific origin of the case must remain undetermined.

(11) In Havana a majority of the cases of enteritis proceed from infections occasioned by intestinal microbes. Next in frequency come the intoxications through ptomaines contained in milk or in other articles of food. Third in order are those occasioned by malaria and influenza. Such is the upshot of our most careful inquiries.

(12) The treatment must depend both on the nature of the cause and on the clinical form of the morbid process. (*a*) First in rank stand purgative medicines, calomel in particular. Next intestinal antiseptics, water diet, and scrupulous alimentary hygiene. (*b*) If malaria or influenza be suspected, quinine must be given. (*c*) Attention to particular symptoms and their appropriate treatment must not be omitted.

(13) The success of the treatment will often depend on a timely intervention on the part of the physician, and also on such a selection of therapeutic agents as a sufficient experience of infantile ailments is likely to suggest.

## TYPES OF GASTRO-INTESTINAL DISEASE PREVALENT IN NEW YORK.

By FLOYD M. CRANDALL, M. D.,

*Lecturer on Diseases of Children, New York Polyclinic.*

No region or country is exempt from the gastro-intestinal diseases of young children. In rural districts, where breast feeding is the rule, or where artificial food is obtained fresh and pure, they are at a minimum. In the crowded centers of population, where the people are herded in most unhygienic surroundings; where weak and puny children are born by the thousand in homes of poverty and vice; where artificial feeding is common; where milk is contaminated and many hours old when first received, they reach their maximum. In New York over 30,000 young children have died of diarrhœal diseases during the last decade. From June to October the dispensaries are crowded with these little patients. The physician who practices among the well-to-do sees less of these disorders, for his families flee from the city and its dangers during the hot weather, but no general practitioner who remains in town escapes them entirely.

It is not my purpose to discuss the etiology of the gastro-intestinal diseases, but rather to study their prevailing types as they present themselves in New York. The character and type of diarrhœa is modified by three factors; climate or season, social conditions, and food. It is not now the common belief that heat, *per se*, causes diarrhœa. That it is a powerful factor indirectly is undoubted, for it lowers the vitality of the patient and favors fermentative changes in milk and the growth of pathogenic germs. Digestive disorders occur during every month of the year, but they do not become prevalent or very serious until June. There is occasionally considerable hot weather in May, but diarrhœa does not prevail to a serious degree. It frequently happens that no case appears in the large dispensaries before the 10th of June. The first case seen at the Polyclinic developed one season on June 10, the next season on June 7, while this year the first case did not appear until June 19. Serious development of the disease does not, as a rule, occur before June 20. It is most prevalent during the first ten days of July, the numbers being but slightly diminished during the second ten days. After July 20 the number of new cases decidedly diminishes. During the six weeks between July 20 and September 1 the development of new cases is remarkably uniform, being less than half that of early July, although the difference of the average temperature of these periods is but one or two degrees. During the first half of September the number of new cases is remarkably diminished, but during the latter half of the month there is a decided increase. The accompanying table shows the date of onset of diarrhœa from June to November.

It would be an error to conclude that these variations are due to heat alone. Observation has abundantly proved that when the mean temperature has reached a certain point (about 60° F.) an increase of temperature is not of necessity followed by an increase of the gastro-intestinal diseases. Numerous factors contribute to the results shown by the chart. One of the most important, it seems to me, is the fact that large numbers of feeble, marasmic babies are ready to succumb as soon as hot weather produces conditions favorable to the development of diarrhœa. It is simply the working of the law of natural selection. The unfit are the first to perish. It must not be supposed that the chart shows the actual number of patients under treatment at any time. Many children who sickened in July continued ill in August. The actual number of children under treatment in August is greater than would be indicated by the chart.

The chart is especially interesting in our present study, as it maps out very clearly marked changes in the type of the disease. During June and early July the prevailing types are those of acute dyspeptic diarrhœa. In grouping these cases I use Dr. Holt's classification in Keating's Cyclopædia. In recording the histories careful

TABLE SHOWING THE DATE OF ONSET OF DIARRHEA DURING FOUR YEARS.

observations were made of the character of the stools and their exact number. Until July 20, twenty or even more stools in twenty-four hours are common. After that date it is rare to find that number. Serous diarrhœa, marked by numerous profuse, thin, watery passages, is common in June and July. In August the prevailing disease is marked by thicker grumous stools much less frequent in number. Acute dyspeptic diarrhœa prevails in July, entero-colitis in August, but in August even dyspeptic diarrhœa shows less tendency to assume a serous type than it does in July.

Early in September diarrhœa markedly decreases, but later in the month there is a decided increase. There is now a third and very radical change in type. The prevailing disease is so-called dysentery. I am well aware that the term dysentery is not, from a pathological standpoint, proper. The term dysenteric diarrhœa expresses, however, the type of the prevailing disease. The passages are very frequent and small. They consist chiefly of thick mucous and blood and are accompanied by true tenesmus, high fever being present as a rule. These cases are frequently found grouped in certain tenement houses, or in certain streets, and are apparently due to some contagious influence. A chart for 1889 would show the September rise far more marked than the one before you. Observation during the past four summers confirms the view which I expressed in a paper read in 1890 that there are three quite distinct periods. The first begins about the middle of June and terminates about the middle of July, in which diarrhœa is more prevalent than at any other time, the serous type being common. The second extends from the last of July to the middle of September, during which comparatively few cases develop. The number of cases under treatment, however, is large, for entero-colitis is common, dating back, in many instances, to a dyspeptic diarrhœa in July. The third period occurs during the latter part of September, in which the cases are largely of a dysenteric type.

I have been unable to demonstrate that age has any material effect upon the type of the disease. The statement that very young children are especially prone to serious diarrhœa has not been born out. Of patients suffering from dysenteric diarrhœa over 80 per cent were under 14 months. That form of the disease seems prevalent chiefly among infants and children of 10 or 12 years. As an etiological factor, age is very important. I showed in the paper referred to that in 3,000 cases occurring in New York 84.1 per cent of the patients were under 2 years of age, and 53.2 per cent were between 6 months and 18 months.

The following observations were made upon 541 patients during the four years beginning with 1889. A history of disordered digestion preceding the diarrhœa, as slight diarrhœa, constipation, or indigestion, was obtained with certainty in 41 per cent of the dyspeptic cases. In a very large number of cases previous condition could not be obtained with certainty. Entero-colitis was almost invariably preceded by diarrhœa more or less continuous for a period ranging from a few days to several weeks. Well-defined entero-colitis develops with extreme rarity in perfectly healthy children. The onset was sudden in 72 per cent in the dyspeptic cases. It was frequently so definite that the mother could state the day and hour at which the first symptoms appeared. In the remaining cases the onset was gradual or uncertain. In entero-colitis the exact date of onset or transition from dyspeptic diarrhœa could be determined in but 20 per cent of the cases. The onset of well-marked dysenteric diarrhœa was sudden and definite in over 90 per cent of the cases. A curious fact was developed in this connection in studying the cases of two years. The interval between the onset of the diarrhœa and the first visit to the physician was found to be in June 4.3 days, in July 3.8 days, and in August 2.9 days. Hence, in August the child was brought for treatment almost one and one-half days earlier than in June. This is perhaps explained upon the ground that mothers did not appreciate the dangers of diarrhœa in June. In August, warned by personal experience or that of their friends, they sought medical aid earlier.

The number of passages per day was noted in 438 cases. In dyspeptic diarrhœa

they varied from 2 or 3 per day to 20, 30, or more, the common range being from 6 to 15. In entero-colitis the extremes were about the same, but the usual number was more constant, ranging from 8 to 12. In dysenteric diarrhœa the extremes were 8 to 40, the average number being large; 12 to 20. Within certain limits the number of passages is not a criterion of the seriousness of the disease. Some of the most serious and fatal cases which confront us are those in which the passages are large but not watery, of excessively offensive odor, and occur only at intervals of several hours. There may be but 2 or 3 in a day. They show a tendency to group themselves. An interval of five or six hours, or even longer, will pass with no passage. Then 3 or 4 will occur in quick succession, to be followed by another long interval without passages. The temperature in these cases ranges high and the constitutional disturbance is profound. The natural tendency is to terminate in death by toxæmia. This type is not uncommon in New York. It illustrates very forcibly the fact that diarrhœa is, strictly speaking, a symptom, not a disease. Here we have excessive decomposition of the intestinal contents with grave constitutional disturbance, with very slight diarrhœa. The physician whose sole object in the treatment of these disorders is to check diarrhœa would lose cases of this character. The diarrhœa is a conservative process and is to be encouraged.

Allied to these cases are those in which the symptom of diarrhœa appears late. The child is fretful, restless, and apparently ill, with more or less fever. This condition will continue for several hours—sometimes twelve hours or more—the bowels being constipated. When at last they do act, either naturally or as the result of a cathartic, the physician suddenly finds that he has a fully developed dyspeptic diarrhœa to deal with. The temperature is sometimes very high, and the diagnosis is uncertain until large grumous, foul-smelling passages indicate the nature of the disorder. The temperature usually falls when the bowels act, but as a rule, unless active measures are taken, recovery does not occur.

Diarrhœa of the serous type is common early in the season, as we have already seen. It is not, however, true cholera infantum. It seems to me unwise to apply that term to ordinary summer diarrhœa. Cholera is a disease characterized by certain peculiar symptoms, and the term cholera infantum should be restricted to a well-marked but rather rare type of disease simulating cholera. I have seen in New York but five or six well-marked and typical cases of this class. In the western part of the State of New York it is somewhat more common than in the city. I would restrict the term to a disease which appears suddenly and is marked by frequent and profuse watery passages, which quickly drain the fluid from the body and reduce a strong child in a few hours to a state of extreme danger. The temperature ranges high. Constitutional disturbance is profound. Prostration is alarming. The whole aspect of these cases, as I have seen them, is entirely different from that of ordinary dyspeptic diarrhœa, even when the stools are large and serous in character.

The color of the passages varied from the clear, watery, colorless stools of cholera infantum and yellowish, watery, serous passages to yellow, green, brown, and black. Green more or less decided, appeared at some period in 71 per cent of all the cases. Blood was present in the passages at some time in 29 per cent of the inflammatory cases, not including the dysenteric, but was rarely profuse. It appeared in at least 13 per cent of 274 dyspeptic cases, usually at the outset, and was several times profuse. The idea that blood is a symptom of inflammation or of lesions has no foundation in fact. In several instances the blood appeared in the first passage, but soon ceased, and the patient recovered without any symptoms of inflammation. Vomiting was present in 63 per cent of the dyspeptic cases. It usually occurred early and frequently ceased after the first day or two, but was often persistent. It was more common in cases marked by watery passages and not infrequently preceded the diarrhœa. Vomiting occurred in 43 per cent of the inflammatory cases. It was not often persistent or continuous, nor as troublesome as in the preceding type.

Pain is a somewhat uncertain symptom in young children. In dyspeptic diarrhœa it was sometimes abdominal and griping, but more commonly seemed to be of a bearing-down or straining character. There was frequently abdominal tenderness, but this was by no means a constant symptom. Pain was evidently present to a greater or less degree in most of the inflammatory cases. It was commonly of a bearing-down nature, and was sometimes a true tenesmus, accompanied not infrequently by a partial or complete prolapse of the rectum. Abdominal tenderness was, as a rule, present, usually in the umbilical or right iliac region, but distension or tension of the abdomen was not constant.

Temperature records in dispensary patients are necessarily imperfect. Seventy-two per cent of the dyspeptic cases questioned gave a history of fever or feverishness, usually at the outset. Only 21 per cent of the whole number, however, showed a temperature of more than  $100^{\circ}$  at their first visit. It was frequently normal. In the septic type already described, marked by infrequent, offensive passages, the temperature ranged high throughout, occasionally reaching  $105^{\circ}$  or  $106^{\circ}$  in fatal cases. Inflammatory diarrhœa, was almost invariably marked by some elevation of temperature, ranging usually from  $99.5^{\circ}$  to  $103^{\circ}$ . Except in cases of a dysenteric type, it was rarely very high. A slight, somewhat intermitting, but persistent, temperature was the rule in entero-colitis.

From these studies we are able to present the following general description of the gastro-intestinal diseases common to young children in New York: The dyspeptic form is commonly preceded by a disordered state of digestion. The onset may be gradual, but is usually definite and often sudden. Fever is generally present in the early stages, but thereafter is not constant. Two general forms are common, but are not sufficiently distinct to be classed as different varieties. One is characterized by watery, brownish, greenish, or light-colored passages, occurring from 10 to 20 or more times a day, accompanied frequently by vomiting, which is sometimes persistent. This is the so-called serous or choleraic diarrhœa. Classical cholera infantum is a rare disease. The other class, much more common, is characterized by semi-solid passages, composed of fœcal matter, white curdy masses, or undigested food, mingled with serum, mucus, or blood, and of a variable color, but more often green. Fever, pain, and vomiting are frequent. The first form is rarely well defined, but usually originates from the second or merges into it, the same patient presenting at different times symptoms referable to each.

Entero-colitis, as a rule, develops gradually from a dyspeptic diarrhœa. The passages are usually green, and frequently contain blood, mucus, and pus. Pain and abdominal tenderness are commonly present, and not infrequently true tenesmus. Vomiting is common, but not persistent. Fever to a slight degree is invariably present, but, being in some instances intermittent, single thermometric observations may fail to detect it. The course of the disease is extremely variable.

---

## SUR LES DYSPEPSIES DES JEUNES ENFANTS A RIO DE JANEIRO.

Par le Dr. MONCORVO,

*Membre correspondant de l'Académie de Médecine de Paris.*

Les troubles dyspeptiques se présentent avec une fréquence exagérée chez les enfants au Brésil. Il y a lieu d'admettre deux groupes distincts de gastropathies dans l'enfance: un premier groupe qui comprend celles provenant exclusivement des écarts de régime alimentaire (allaitement naturel vicieux, allaitement artificiel, sevrage prématuré, alimentation grossière ou mal distribuée, etc.), et un autre où les troubles dyspeptiques sont engendrés primitivement par l'affaiblissement général de l'organisme ou par un état encore presque physiologique comme il arrive par l'anémie tropicale et l'impaludisme latent. Dans des cas pareils les enfants peuvent

devenir dyspeptiques, encore même qu'ils soient maintenus à un régime alimentaire bien dirigé.

Il est inutile d'ajouter que, dans les cas de ce genre, les maladies dystrophiques héritées ou aqueuses jouent le rôle assez important de cause prédisposante.

Enfin, on pourrait ajouter aux précédents un troisième groupe des troubles gastro-intestinaux d'ordre secondaire, presque inséparable à la plupart des maladies aiguës de l'enfance, et d'un grand nombre d'affections chroniques propres à cette période de la vie.

Les désordres du premier groupe sont chez les nouveau-nés annoncés tout d'abord par les caractères des garde-robes, ensuite par l'intolérance gastrique; ce sont des selles plus ou moins fluides, granuleuses, verdâtres, renfermant une assez forte proportion de mucus, des granulations graisseuses et des caillots de caséine non digérée. Elles sont très fétides dans la majorité des cas; c'est l'odeur acide qui attire tout de suite l'attention de ce côté. Enfin le papier de tournesol décèle l'acidité de ces matières. Lorsque le régime vicieux agit d'une façon constante, les désordres s'aggravent de plus en plus, et bref, on a sous les yeux le tableau saisissant de l'athrepsie de Parrot. Il convient d'observer que celle-ci est bien loin d'avoir ici la fréquence signalée ailleurs, et cela semble tenir en quelque sorte à ce qu'au Brésil il n'est point fort commun de voir l'allaitement artificiel adopté exclusivement pendant les deux ou trois premiers mois de la vie. Le lait de la mère ou de la nourrice atténue presque toujours les inconvénients des écarts du régime.

Le sevrage prématuré, l'administration d'aliments lourds et grossiers, donnent ordinairement lieu aux troubles dyspeptiques retrouvés aux autres périodes de l'enfance. C'est alors qu'il est très fréquent de voir ces accidents digestifs coïncider avec la dilatation du ventricule. La gastro-ectasie que j'ai décrite le premier, en 1882, chez les jeunes sujets, est ici d'une fréquence bien supérieure à celle constatée, après mes travaux, à l'étranger, notamment en France et en Allemagne.

Chez les tout jeunes sujets dyspeptiques, les troubles digestifs se dénoncent d'abord par la longueur de la digestion gastrique; l'estomac qui, dans les conditions physiologiques se vide parfois avant une heure après chaque tétée, renferme encore du lait coagulé une heure et demie à deux heures même après. Cette digestion languissante va se compléter ensuite dans le duodenum, mais dans un assez grand nombre de cas la peptonisation y est encore imparfaite, ce qui explique la présence dans les garde-robes d'une certaine quantité de caséine (lientérie). Cette stagnation du lait dans le ventricule entraîne naturellement à la longue la dilatation de cet organe, notamment lorsque les désordres chimiques se produisent chez un enfant dystrophique ou affaibli par quelque maladie intercurrente. Dans ce cas, la gastroectasie obéit à des causes complexes dépendant tant de la réplétion ventriculaire que de l'atonie de la couche musculaire, dont l'excitabilité s'épuise si promptement à l'âge dont je m'occupe.

Jusqu'à ce jour le meilleur réactif pour bien juger des fonctions digestives des nourrissons était l'aspect et la composition des selles. A vrai dire, l'examen des garde-robes rend assez de services au diagnostic des troubles gastro-intestinaux, mais les progrès de la chimie biologique vinrent jeter assez de lumière à l'étude du liquide gastrique au cours de la digestion. Je fus donc tenté d'explorer le suc gastrique chez les jeunes sujets en utilisant pour cela des réactifs colorants, tels que la tropæoline (oranger-poirier No. 4), indiquée par Van der Velden, le violet de méthyle par Laborde, le vert brillant employé par Jachs et Lepine, et surtout le phloroglucine-vaniline conseillée par Güntzbourg de Frankfort et par G. Sée. Enfin, j'ai eu également recours au réactif de Boas, c'est-à-dire une solution alcoolique à 5 pour cent de résorcine additionnée de 3 pour cent de sucre de canne. Tous ces réactifs furent employés à la recherche du suc gastrique. J'ai adopté le réactif d'Uffelmann pour celle de l'acide lactique.

La recherche de l'acide chlorhydrique libre doit être pratiquée vers la fin de la période ordinaire de la digestion, car avant cela la réaction alcaline du lait s'y

oppose, ainsi qu'il est facile de constater au laboratoire. L'acidité du liquide gastrique peut être due avant cela à la présence de l'acide lactique; on en doit tenir compte pour se soustraire à des erreurs.

Dans mes recherches, je rangeai dans un premier groupe des petits sujets n'ayant pas dépassé la première année; dans un second je rassemblai ceux de la deuxième année; enfin un troisième groupe comprit les enfants de deux à sept ans.

Ces sujets étaient presque tous hérédosyphilitiques, paludiques, vivaient dans des mauvaises conditions hygiéniques et présentaient tous des désordres gastro-intestinaux. D'après mes examens répétés chez eux par rapport à la composition de leur suc gastrique, j'arrivai à cette conclusion que le déficit de l'acide chlorhydrique y constitue la règle. L'extrême efficacité de la chlorhydrothérapie dans les cas de ce genre ne fait que confirmer les résultats des recherches chimiques. C'est donc l'hypochlorhydrie ou l'anachlorhydrie qui explique l'imperfection gastrique chez les jeunes enfants.

Un fait semble résulter aussi de cette expérimentation clinique: c'est le rôle important que joue le ventricule dans la digestion des nouveau-nés; au contraire de ce qu'ont prétendu affirmer certains pédiatres. Au fait, dans les cas où les troubles digestifs deviennent assez accusés, il est très commun de retrouver dans le ventricule du lait coagulé, deux heures et plus après son ingestion; ce qui démontre l'imperfection de la digestion gastrique. Enfin, la disparition de la lientérie, à la suite de la chlorhydrothérapie, semble bien le confirmer.

Les cas d'hyperchlorhydrie ne sont, à cet âge là, que des faits exceptionnels, du moins d'après mon observation personnelle. Il faut, en tous ces cas, établir une distinction entre l'anachlorhydrie ou l'hypochlorhydrie passagères, dues à des causes accidentelles et transitoires dans le cours même d'une santé florissante, et le déficit chlorhydrique permanent qui constitue une affection bien établie et d'une durée qui est presque toujours loin d'être courte. C'est dans les cas de cette nature que se présente cette lientérie presque constante qui tend parfois à s'éterniser. La lientérie est donc un facteur fort digne de remarque dans la séméiologie des troubles dyspeptiques à cette époque de la vie. Ce fait a été déjà signalé par moi, en 1877, dans un mémoire concernant la lientérie dans l'enfance. J'y ai mis alors en relief l'influence probable de la chaleur sur le déficit chlorhydrique, tout en comparant la situation de mes petits sujets à celle étudiée par Gallard en France chez les individus obligés par leur profession à vivre dans un milieu trop chaud.

Chez les enfants du deuxième groupe, la lientérie est également un phénomène fréquent et coïncide presque toujours avec la dilatation gastrique. Cela se voit plus souvent chez les sujets dystrophiques et porteurs de troubles digestifs de date ancienne.

---

## APPENDICITIS IN CHILDREN.

By JOHN B. DEEVER, M. D.,

*Professor of Surgery in the Philadelphia Polyclinic; Assistant Professor of Surgical Anatomy in the Medical Department of the University of Pennsylvania, etc.*

I have selected the subject of appendicitis in children as my contribution before this section for the following reasons: First, because the disease is one which occurs frequently in early life, and, from some similarity of symptoms, is likely to be confused with and mistaken for some one of the various intestinal disturbances peculiar to children; second, because the gravity of the disease is such that upon its early recognition depend in a great degree the chances of recovery; third, because I desire to advocate the removal of the appendix in the acute primary attacks as soon as the disease is recognized, where there has been no decided response to judicious medical treatment, and between attacks in all recurrent cases.

In a paper read before the last meeting of the American Surgical Association I maintained that all inflammations located in the right iliac fossa have their origin in the appendix, such a conclusion being the inevitable result of observations at both the operating and post-mortem tables. I also proposed that the terms typhlitis, perityphlitis, and paratyphlitis should be expunged from the medical vocabulary as being misleading in their character and as presenting a classification which is anatomically unfounded, and which clinically is incapable of demonstration. I would therefore group under the terms appendicitis all inflammatory conditions of the right iliac fossa, believing that in so doing a clearer conception will be formed of the true pathological conditions present, and that a common treatment, that of early operative interference, will be adopted universally.

All cases of appendicitis may be classified under the following heads: Catarrhal; ulcerative, which may be the result of a circumscribed catarrhal inflammation or of an obstruction due to the presence of a foreign body, as a faecal concretion, an enterolith, a stricture, etc.; perforative, an advanced stage of the ulcerative type; tubercular; and relapsing or recurrent.

*Pathological changes.*—The pathological changes occurring in cases of appendicitis vary according to the exciting cause, but are usually those common to inflammations of the intestinal tract, and may present any of the conditions from a simple lymph exudate to a pus formation.

*Ætiology.*—Inflammation of the appendix may be the result of either predisposing or exciting causes. Among the predisposing causes age is an important factor, 15 per cent of all cases occurring under 15 years. The youngest case I have met with was in a child 2 years old. Males are more prone to the disease than are females. A tubercular diathesis is not uncommonly the remote cause of a suppurative appendicitis. Chronic constipation is a further predisposing cause, which may induce either a catarrhal or an ulcerative type. Among the exciting causes may be mentioned the presence of seeds, enteroliths, faecal concretion, inspissated mucus, particles of undigested food, traumatism, and exposure to cold or dampness, but the most frequent exciting cause is the result of a previous attack.

*History and symptoms.*—The onset is usually sudden, constipation the rule rather than the exception. We may be able to elicit a history of one or more previous attacks or of the rapid ingestion of some indigestible substance or overloading of the stomach. The symptoms of appendicitis in its incipency are not by any means definite in all cases. The prominent and constant symptoms are pain, vomiting, and tenderness. The pain which is at first paroxysmal, in this respect resembling colic, is referred to the umbilical and epigastric regions, and in 72 per cent of all cases appears within twenty-four hours. Later it becomes continuous, and is localized in the right iliac fossa in 54 per cent of all cases. Vomiting is present from the first, becoming uncontrollable if the case does not yield to treatment. The vomited matter consists first of the contents of the stomach, later of bile, and finally, if a plastic peritonitis supervenes by which the coils of intestines are immobilized from the resultant deposit of lymph, of stercoraceous matter in those cases in which the intestinal tract has not been emptied. Ordinarily the vomiting of stercoraceous matter is indicative of acute intestinal obstruction, yet we see stercoraceous vomiting in advanced and hopeless cases of appendicitis. The tongue is furred, and later in the disease becomes dry, with the deposit of sordes upon the teeth. There is extreme thirst, with a temperature varying from 102° to 104° F., and a high pulse rate. The bowels are usually confined; it is, however, not uncommon to have the disease ushered in with diarrhœa. The presence of sick stomach, diarrhœa, and pain coming on suddenly are suggestive of enteritis, the affection with which acute appendicitis in its incipency is most likely to be confounded. As the affection advances, the child frequently favors the affected side and lies with the thigh of the corresponding side flexed upon the abdomen. Frequency of urination is often a prominent symptom, being due evidently to the involvement of the sympathetic nerves.

Examination by palpation reveals general tenderness over the affected area, while the point of greatest intensity usually corresponds to the so-called McBurney point, providing the appendix occupies its most common position, arising from the postero-internal aspect of the base of the cæcum. I recall one case in particular where the greatest point of tenderness was immediately above the middle of Poupart's ligament. This, as demonstrated at the operation, corresponded to the angle of curve in the appendix which arose from the postero-external aspect of the base of the cæcum and descended in front of it as far as its apex, when it turned abruptly upward. When general peritonitis is present early, as in the perforative variety of the disease, notwithstanding that there is a very general abdominal tenderness, yet upon deep pressure a point in the right iliac fossa corresponding to the appendix can be made out which is much more painful than any other point in the abdomen. Palpation also detects very decided resistance offered by the abdominal muscles of the affected side. In many cases an indurated mass is to be felt, which is circumscribed or diffused, particularly in the direction of the linea alba and of the pelvis. Superficial percussion in the early part of the disease yields negative information, while deep percussion, if the case steadily advances, will reveal dullness and later flatness. Deep rectal as well as vaginal examination I do not think of much diagnostic value, early in the disease at least. In those cases where the appendix projects into the pelvis it may be of some assistance. If a mass can be felt through the rectum or the vagina, palpation of the abdominal walls at the same time may elicit fluctuation. Suppuration is not always readily detected, as fluctuation is difficult to elicit on account of the unyielding abdominal wall. Yet I have seen it well pronounced many times. Edema of the overlying abdominal walls is of great diagnostic value as indicating the presence of deep suppuration. If, associated with the presence of a mass in the right iliac fossa, there are decided chills, or even chilly sensations with sweating, it is quite evident that pus is present.

*Diagnosis.*—The establishment of a diagnosis depends on the character of the symptoms, the clearness of the history, the duration of the disease, and the previous treatment, as the administration of opiates to relieve distressing pain may mask many symptoms which would otherwise be prominent. The affections with which appendicitis is most likely to be confounded in children are enteritis, involving all the coats of the intestine (enteroperitonitis); acute mechanical intestinal obstruction; perinephritic abscess; abscess of the kidney, and especially so if the kidney be a floating one, as I have once observed; psoas abscess; iliac abscess; abscess of the abdominal parietes; hip disease, hepatic and renal colic. In enteritis, involving all the coats of the intestine, the disease is ushered in by a diarrhœa of a more or less severe type, in which the stools are watery and mucoid in character. This is accompanied by pain of a colicky nature referred to that portion of the abdomen corresponding to the situation of the affected coils of intestine; also by the absence of abdominal distention. Later, however, when the muscular and serous coats are invaded by the inflammatory process as a consequence of the infiltration and the involvement of the sympathetic nerve filaments supplying the coats of the bowel, paralysis of the bowel occurs which results in distention. Diarrhœa is now no longer present, but on the contrary, absolute constipation with inability to pass flatus. Vomiting occurs, which if the disease is not relieved become stercoraceous. Ordinarily there would be but little trouble in differentiating between this form of enteritis or entero-peritonitis and appendicitis if the symptomatology of the latter affection is borne in mind, in addition to what has been said about the physical signs elicited by careful abdominal palpation in cases of appendicitis.

In acute mechanical intestinal obstruction the two most common forms met with in children are invagination and strangulation by bands; the onset of the symptoms is much more abrupt and severe than they are in appendicitis. In invagination, as in strangulation by bands, the pain, which is most intense and at first occurs in exacerbations, is referred to the seat of the obstruction, or more commonly to the umbilicus, and not concentrated in the right iliac fossa, as is the case in appendicitis.

when the disease is well established. There is absolute constipation with inability to pass flatus. Vomiting is an early symptom in both forms of obstruction, which, if not relieved, becomes stercoraceous. When peritonitis supervenes there is very little effort attending the vomiting. Properly speaking, the patient at this stage of the disease regurgitates fecal matter, caused by the reversed peristalsis. There is absence of fever in strangulation by bands and in invagination unless the child survives until the invaginated portion of the bowel commences to undergo inflammation, which causes ulceration and affords nature a means of disposing of the intussusceptum, and thus establishing a spontaneous cure. In invagination the presence of a movable tumor, the most common site of which is to the left of the middle line, but not always to be made out on account of the distension, while in appendicitis a tumor, if present, is fixed and always occupies the right iliac fossa, are important differential points. In invagination a discharge of blood and mucus from the rectum, and in many instances the presence of a tumor, may be detected upon making a digital examination of the rectum. With the development of peritonitis in acute intestinal obstruction there is marked distension of the abdomen. Collapse is an early symptom in acute intestinal obstruction, while not so in appendicitis unless it be of the perforative or fulminative variety; but even then it is a later manifestation than in obstruction. In perinephritic abscess the location of the swelling, the presence of edema in the loin, and the absence of bowel symptoms are important differential factors. In many cases of perinephritic abscess the trouble is preceded or accompanied by the presence of pus as well as other abnormalities in the urine. This is not, however, true in those cases which have their origin independent of the kidney, as when due to constipation, traumatism, etc. In perinephritic abscess, as in some cases of appendicitis, owing to the relation between the perinephritic tissue, the appendix, and the psoas magnus muscle, flexion of the thigh upon the abdomen is a symptom common in both affections. If a doubtful case should arise where it would seem to be impossible to differentiate, better than introducing an exploring needle or an aspirating needle, either of which procedures under these circumstances I regard as most unsurgical and attended by no little danger, I would advise an exploratory incision in the loin before cutting through the abdominal wall anteriorly. This could not possibly result in any harm, even if the perinephritic space be found intact; nor would it interfere in the least with immediately cutting down upon the appendix. In abscess of the kidney the same train of symptoms is largely present as in perinephritic abscess, namely, a mass in the loin corresponding to the position of the kidney, pus in the urine, history of renal colic, with perhaps the passage of small crystals of uric acid; yet, to have renal colic it is not necessary that a stone or a fragment thereof should pass through the ureter, but simply a plug of fibrin or inspissated mucous, as I have seen upon several occasions in cases of pyelitis. In kidney abscess, nausea, with sometimes vomiting, is a not inconstant symptom. In the absence of urinary symptoms, abscess of the kidney, and particularly if it be one of a floating kidney, the differential diagnosis is necessarily more difficult. In the latter instance, however, the tumor will be movable; a point to be borne in mind. I have recently operated in the case of an acute supuration of the kidney where the urine was normal and where the diagnosis was made purely upon the anatomical situation of the swelling. In psoas abscess the onset is slow, with little or no fever, usually, though not always, accompanied by evidence of disease of the vertebræ, absence of pain, tenderness, and bowel symptoms. There may be flexion of the thigh of the corresponding side due to the muscular irritation. What has been said of psoas is equally true of iliac abscess, if dependent upon bone disease. Should a collection of pus in the iliac fossa be dependent upon disease of the uterine appendages, a vaginal examination would reveal the cause. In the latter variety of abscess, however, the swelling usually holds a lower position than abscess, the result of disease of the appendix, it being near Poupart's ligament, in fact, immediately above it.

*Abscess of the abdominal wall.*—Between abscess of the abdominal wall and that caused by appendicitis there should be but little difficulty in arriving at a correct conclusion. If the collection is in the superficial fascia it will be circumscribed, while if between the abdominal muscles it is likely to be diffused. The purely local character of the abdominal abscess, the swelling moving with the abdominal walls, the absence of intestinal symptoms, the presence of local and constitutional evidence of pus, coupled with the history of the case, should be enough to render a differential diagnosis possible.

*Hip-joint disease.*—The presence of the characteristic deformity, inability to execute the normal movements of the joint, pain referred to the knee, arching of the lumbar spine when the limb is brought into the fully extended position, absence of intestinal symptoms. If there is still doubt, the administration of an anæsthetic will suffice to dispel it.

*Hepatic colic.*—In hepatic colic the painful area is usually higher in the abdomen, radiating toward the shoulder, most severe over the region of the gall bladder, and usually followed by jaundice.

*Nephritic colic.*—In nephritic colic a history of previous attacks may often be obtained. The origin of the pain is deep in the upper loin, radiating in the line of the ureter, with retraction of the testicle, diminished urinary flow, with blood or pus, and a sudden termination of the attack. Retraction of the testicle may occur in appendicitis, due to irritation of the genito-crural nerve. I recall a case of a physician in which the diagnosis of renal colic had been made, and in which the ureter was supposed to have been ruptured by the passage of a calculus. The autopsy revealed a gangrenous and perforated appendix, with diffuse suppurative peritonitis.

*Prognosis.*—The age of the patient has a material effect upon the prognosis. The earlier in life it occurs the less resisting power is exhibited by the patient. Sex does not seem to be a factor. Where an abscess forms and ruptures or perforation takes place, and the contents of the bowel escape unconfined by a wall of lymph, general peritonitis is rapidly established, terminating these cases with a fatal uniformity. The most favorable point for spontaneous evacuation of the contents of an appendicular abscess is into the cæcum. Rupture into the rectum is also followed by recovery in the majority of cases. Rupture into the bladder is fatal in about 50 per cent of the cases. The most favorable results have been recorded where early operative interference was instituted, the mortality under this plan of treatment being but 6 per cent.

*Treatment.*—The first indication to be fulfilled in a case of appendicitis, or even of a supposed case, is to obtain a free action of the bowels. This is best accomplished by the administration of small and repeated doses of salines, preferably Rochelle salts, or, if the stomach is not tolerant of salines, small doses of calomel. The free evacuation of the bowels, not drastic purgation, serves the purpose of clearing the alimentary canal of all foreign and irritable substances, as particles of undigested food, etc.; relieves the congested blood vessels, thus modifying the degree of the subsequent inflammation, and again fulfills a most important indication in having the bowels in the most favorable condition for operation in the event of its necessity. I can not emphasize this important part of the treatment too strongly, as upon it, I believe, largely depends the chances of the patient's recovery. Certainly, in my experience, the bulk of the cases I have seen recover without operation have been those where it was most thoroughly carried out, and in the cases operated upon the largest percentage of recoveries have been in those where the bowels were not allowed to be confined. Where there is great pain, as we frequently see, in addition to the administration of salines or calomel, as the case may be, we may be forced to use anodyne, and, if so, it should be given in the smallest possible dose.

The pain in appendicitis, which is colicky in nature, is due first to the muscular contraction of the appendix and the bowels, and in the majority of instances is pro-

voked by irritation within both. Therefore, is not the evacuation of the intestines of their irritating contents urgently called for? Are they not, in other words, asking to be relieved? This being so, will not purgation take the place of an anodyne, as a hypodermic of morphine, which is so often and indiscreetly given? In other words, the best anodyne is the repeated dose of salts or calomel, which does more than any preparation of opium can do, both relieving and removing the cause of the pain. Recognizing the character of the pain, is it not possible to afford relief by hot applications to the abdomen in the shape of the hot-water bag, hot cloths, hot turpentine stupes, etc.? Internally, before giving opium, I prefer to use spirits of chloroform, carminatives, or extract of belladonna. If now relief is not obtained, then I administer a small dose of opium, and preferably by suppository, as I think we all agree that opium given in this form is less liable to cause sick stomach. Sick stomach is so frequently provoked by morphine given hypodermically that it is often difficult to say whether the nausea or vomiting is due to the morphine or to the disease. Further, there is no disputing the fact that opium, or any of its preparations, brings about a paretic condition of the bowel, and thus favors distention, an obstacle difficult to contend with when endeavoring to elicit a mass.

If the case be catarrhal, the presence of congestion of the mucous lining of the appendix is the exciting factor in occasioning contraction of the muscular coat, which is the direct cause of the initiatory pain. Again, as has already been noted, emptying the bowels freely both removes an additional factor in exciting contraction of the muscular coat of the appendix as well as depletes the circulation and renders the canal more patulous and better able to free itself of mucus, which, if retained, becomes inspissated. The presence of inspissated mucus in catarrhal appendicitis is liable to lead to an ulcerative type of the disease. While I do not believe the good derived from purgation in the obstructive form of appendicitis is equal to that in the catarrhal type, yet I do not know of any other form of medication capable of accomplishing the same amount of good. There is some hope, too, in emptying the cæcum that the orifice of the appendix may be rendered patulous and the expulsion of the foreign body facilitated. In the perforative and explosive or fulminant varieties of the disease, the latter being only a difference in degree of the former, active purgation would be ill-advised on account of the fear of hastening and making greater the extravasation of fecal matter. The treatment by free evacuation of the bowels may be thought to be erroneous on account of the increased peristalsis resulting therefrom, aggravating the already existing inflammation. The use of leeches and blisters is advocated by many in preference to purgation to accomplish depletion of the circulation. I must confess this is not in accord with my experience. Blisters, I think, are particularly objectionable on account of the infiltration of the skin they occasion, which both interferes with palpation and the recognition of pus by the edema of the abdominal walls.

The question of diet throughout the disease is important, and it should consist—until the patient is convalescing, at least—of peptonized milk, koumyss, milk, and apollinaris or carbonated lithia water, liquid beef peptonoids, and concentrated beef tea, the latter being all the more indicated on account of its laxative effect. Buttermilk I find very grateful to many patients. As to the propriety of the removal of the appendix in cases of recurrent appendicitis, there is, in my mind, no doubt. While I am willing to admit that my experience has taught me that acute attacks of recurrent appendicitis are less fatal than primary appendicitis, yet I can not see how this argues against removal of the appendix between attacks, the period for elective operation. I am unable to understand the philosophy of the argument that because a patient has survived a number of attacks of recurrent appendicitis the appendix should not be taken out, since each recurring attack may possess elements of danger unknown to us which may deprive our patient of his life. Those of us who have observed these cases carefully know that many are the subjects of chronic invalidism. The percentage of mortality in operations for recurrent appendicitis in

skilled hands is less than 1 per cent. The absence of inflammatory conditions so simplifies the operation that its after conduct entitles it to be classed as a simple wound. This same absence of acute inflammatory condition which relieves the necessity for drainage and the consequent impairment of the integrity of the abdominal walls lessens in a great degree the liability to ventral hernia.

The after treatment of these cases is so simple that it deserves special mention. It consists during the first three days of alimentation alone, absolutely no opiate, and at the expiration of this time, if the bowels have not moved voluntarily, of the administration of one-tenth grain doses of calomel every hour or two until a desire to defecate is produced, when an enema is given.

Before discussing the operative treatment of this disease, and while advocating the most radical methods, I desire to disclaim any intention of declaring that all cases where the ordinary medical treatment of the general practitioner has failed to afford relief are cases for immediate operation, as I believe that such a decision should rest only with an experienced surgeon, who may have carefully observed the progress of the case. Further, that the operation should be done by one who is thoroughly prepared to dispose of any of the unlooked-for conditions which are likely to be met with in any case. The skill required for the rapid and thorough performance of appendicial operations must be of the highest order, as time lost and prolonged etherization (by which the patient becomes, as it were, water-logged) during an operation may be just sufficient to turn to a fatal termination what would otherwise have been a successful result. This is of special importance when operating upon children, as we well know they do not bear prolonged etherization or operation. In the gravest types of the disease, when there is a sudden abatement of the symptoms, the attending medical man or surgeon, as may be, must not congratulate himself upon the rapid recovery of his patient and overlook the fact that this is a forerunner of perforation. On the contrary, if operation has not already been entertained, the strongest indication for its immediate performance now presents itself. Following this period (which is practically one of shock) in the course of a few hours, usually 24, a general peritonitis has developed and the golden opportunity for offering the patient his only chance for relief is a thing of the past.

The technique of the operation for appendicitis where abscess exists varies by reason of the different local conditions found. When the abscess is circumscribed and shut off, after the pus has been evacuated and the cavity irrigated, if the appendix can not readily be found it is not judicious to make a prolonged search for it, by which the limiting wall may be broken through and a communication with the general peritoneum established. In this class of cases, however, I have been fortunate enough in most cases to find the appendix and remove it without breaking through the abscess wall. This is always more satisfactory to the surgeon than to complete the operation by simply draining or packing the abscess cavity, and it removes what may be the cause of one or more attacks of the relapsing variety of the disease. When the abscess is in communication with the general peritoneal cavity a more prolonged search for the appendix may be made with less risk than in the preceding state, but the patient's general condition is usually so bad under these circumstances as to make it unwise to keep him under the effect of the anæsthetic any longer than is absolutely necessary.

The points I observe in making the incision for the removal of the appendix in acute cases where there is present a mass, be it pus or exudate, are the following: When the loin is rendered prominent by the mass or is the seat of edema, I take it as an indication that the appendix holds a post-cæcal or an external antero-lateral position, or that it comes off from the apex of the cæcum, and I carry the incision parallel with and a short distance above the outer third of Poupart's ligament, prolonging it outward if necessary. When the mass presents itself well to the inner side of the anterior superior spine of the ilium I carry the incision through the semilunar line, rather, through the rectus muscle immediately to the inner side of

the semilunar line. The wound when carried through the muscle heals more solidly, and therefore there is less likelihood of the development of a ventral hernia than when made through the semilunar line.

In acute cases the treatment of the stump of the appendix will depend on its situation and the mobility of the cæcum; if the latter has become fixed through plastic adhesions, and it is not deemed advisable to make the manipulation necessary to bring it well up into the wound, the appendix is tied off *in situ*. If, however, it is possible to present the appendix in a favorable situation, a circular incision is made through the serous coat half an inch from the cæcum and the serous coat then stripped for the space of a quarter of an inch. The appendix is then tied with fine silk, the serous covering replaced with edges inverted and brought together with a Lembert suture. The latter disposition of the appendix is decidedly the most favorable and is the method which we are enabled to employ in cases of recurrent appendicitis with few exceptions. In cases of abscess the pus cavity, when limited, is thoroughly irrigated and drained with either tubes or iodoform gauze, or both combined. When the peritoneal cavity has become generally involved, irrigation and drainage are employed in the usual way.

*After treatment.*—The after treatment in acute cases consists in the administration of small doses of salines repeated sufficiently often to free the bowels, with the same diet as before mentioned, alimentation being allowed immediately on cessation of ether emesis.

#### THE NORMAL PRÆCORDIA IN INFANCY AND CHILDHOOD.

By H. B. WHITNEY,

*Professor of Childrens' Diseases in the Colorado State University.*

It is with great surprise that one finds how little attention has been given to the normal præcordial dullness in infants and children. Upon careful search through all the literature at my command I have failed to find more than two or three brief references to the subject, neither of which approximates to a full and careful statement of the facts. Weil, for instance, whose book on percussion is justly celebrated, simply says that in children below the age of 12 to 15 years the præcordial dullness extends more or less to the right of the right border of the sternum. Cutler and Garland copy the diagram of Weil. Hensch, Baginsky, and J. Lewis Smith give no intimation that the præcordia in childhood differs from that in the adult. Sansom, Fothergill, Loomis, and Guttman make no mention of children. Osler and Cheadle, in Keating's Cyclopædia, are likewise silent. The only author who seems to have given any careful study to the percussion of the heart in infancy is Rotch. In his article in Keating on Pericardial Effusions he states that in infancy the præcordia has the same boundaries as in the adult, while from the second or third up to the ninth or tenth year there is frequently some dullness over the lower half of the sternum.

That the subject merits attention it is hardly necessary to affirm. Endocarditis and pericarditis are not infrequent in childhood, and their diagnosis and differentiation by the aid of percussion depend, as in the adult, upon an accurate knowledge of normal percussion limits. In a child 3 years old a præcordial dullness reaching the second interspace above and extending an inch or more to the right of the median line should cause a strong suspicion of pericardial effusion or enlarged heart; in a child of 8 years such dullness would be normal. Certainly this is an important difference. Again, pleuritic effusions are common enough in childhood, and what more valuable diagnostic feature of effusion than displacement of the heart, particularly toward the right; and yet no diagnosis of slight displacement can possibly be made unless the normal percussion boundaries are known.

The interest of the writer in this subject was first aroused some years ago while

engaged in pædiatric work in Boston. The observation since that time of a comparatively large number of children whose præcordial areas have been for the most part carefully defined has led to the following conclusions:

In children up to the beginning of the sixth year of age the relative dullness of the normal heart has practically the same limits as in the adult, namely, above and to the left, a curved line extending from the junction of the third rib or interspace and sternum outward and downward to the apex of the heart in the fourth or fifth interspace near the mammary line. The right boundary (by far the most important, as being most variable in different pathological conditions) is a perpendicular line corresponding very nearly with the left border of the sternum. The lower half of the sternum is therefore of the same resonance as the upper half in children under 6 years of age.

From the fifth to the ninth year the præcordial dullness varies in different cases. In a few, even at 6 years, some slight dullness will be found over the lower half of the sternum, and in other respects also the præcordia appears to have begun to assume the characteristics presently to be described as peculiar to the latter half of childhood. While at the age of 5 years all cases examined by me presented what for convenience I will term the infantile præcordia, at 6 there were two infantile to every one enlarged. At 7 there was about an equal number of each. At 8 there were three enlarged to every two infantile. And at the age of 9 the infantile præcordia had entirely given place to the enlarged præcordia of the second half of childhood. We may say, then, that beginning with the age of 6 years the cases of infantile præcordia begin to disappear, and that this tendency gradually increases until at 9 years all cases are uniformly enlarged. During this period, therefore, the results of cardiac percussion must often prove equivocal.

In children over 8 years and up to about the age of puberty the limits of the normal præcordia are invariably found to differ widely from those of the first half of childhood and of adult life. In the first place the upper border is generally higher; it is often found as high as the second interspace and occasionally at the second rib. The apex is usually a little outside the median line, perhaps one-fourth to one-half inch. Of far greater significance and clinical importance is the position of the right border of the præcordial dullness. Instead of being a perpendicular line along the left sternal margin, it is now a curved line, which meets the line of liver dullness at a point outside the right sternal edge and usually  $1\frac{1}{4}$  to  $1\frac{1}{2}$  inches to the right of the median line. This distance, of course, gradually diminishes as the upper boundary is approached. The præcordia now presents the form given in Weil's plate, and is somewhat similar to that found in cases of pericardial effusion in the adult.

Some points of importance should here be mentioned as regards the method of percussion. Light percussion only was used in obtaining the above results. A heavy stroke is rarely useful in adults and never in children, where it causes vibrations of distant parts and obscures the tone given by the tissues beneath the finger. Moreover, with the heft of the stroke the degree of accuracy, and especially of uniformity, is diminished. Again, the habit of marking upon the chest the exact point beneath the middle of the finger where the percussion note changes is by no means as puerile as might at first thought appear. Take, for instance, the upper border of a pleuritic effusion: When several marks, made at different points, unite to form a "letter of S" curve the surety of diagnosis is wonderfully increased. So with the heart; marks which lie along regular curves are quite sure to have a meaning. Furthermore, by percussion, first from the center of the præcordia toward the periphery and then backward from normal pulmonary resonance toward the center, it is easy to verify a line once drawn and to arrive at a high degree of certainty of result.

Still a third point of importance I have referred to in previous papers upon percussion of the heart in adults, but it can not be too often emphasized. In the

percussion, namely, of that portion of the heart which lies beneath the sternum, possible under normal conditions only, as already stated, in the second half of childhood, comparison should be made of the resonance of the lower half of the sternum, not with the normal pulmonary resonance along its right border nor with the cardiac flatness along its left, but with the resonance of its upper half, for the sternum is never quite as resonant as the adjoining chest wall; and in percussing from the præcordial center toward the right nipple one might readily suppose that the right border of the normal præcordia extended to the right sternal edge, since there for the first time a full tone is reached, while, on comparing the lower with the upper half of the sternum, it will often be found that the resonance of both is the same. To determine, therefore, whether the right limit of præcordial dullness extends beyond the left sternal border, its normal position in the adult, percussion should be made along the sternum from above downward as far as the horizontal line of hepatic flatness at the level of the sixth rib. Any encroachment of the præcordia upon this right angle formed by the left sternal border and the liver is, except in the latter half of childhood, pathological. It will have been observed that in the foregoing I have made no distinction between relative and absolute dullness. To the latter I attach comparatively little importance, and in speaking of præcordial boundaries I have always referred to the extreme outer limits of cardiac dullness beyond which there is full pulmonary resonance. In the enlarged præcordia of childhood the note elicited over the lower half of the sternum is not flat; it is only moderately dull, and the sense of resistance is but moderately increased. Anything approaching flatness in this region would properly cause suspicion of disease. At just what age this enlarged præcordia of childhood again becomes that of adult life I have been hitherto unable to determine satisfactorily, from lack of sufficient material. Weil, as before stated, says from the twelfth to the fifteenth year. It is an interesting question whether it may not in some cases exist still later than this, and thus cause a semblance of cardiac hypertrophy such as has been occasionally met with in very young men. I have seen several cases of enlarged præcordia in boys from 16 to 18 where there was no discoverable cause and, in fact, no other symptom of enlarged heart. The possibility above suggested should, perhaps, be borne in mind. It would be interesting, certainly, to inquire as to the cause of this comparatively sudden and very considerable increase in cardiac dullness at the seventh or eighth year of life, but I have neither space nor much to offer. Apparently it does not represent any actual enlargement of the heart, since Müller has shown by a series of careful observations that from birth to puberty the growth of the heart keeps about even pace with that of the body.

---

#### THE BACTERIOLOGICAL DIAGNOSIS OF DIPHTHERIA.

By H. C. ERNST, A. M., M. D., of Boston, Mass.

In presenting this paper upon the bacteriological diagnosis of diphtheria, I desire to say at the the outset that my object is not to bring forward anything original, but merely to emphasize the results of much experimental work, and to bring these results more prominently before the profession at large. To agree with the conclusions stated certain points must be considered as proven. These points are, first, that diphtheria is the process, characterized more especially by the formation of false membrane, which is the result of the activity of the Klebs-Löffler bacillus. That this point is settled, is, it seems to me, hardly open to dispute at the present time. Since the original experiments the evidence showing the pathogenic properties of the bacillus first seen by Klebs, and first studied under artificial conditions by Löffler, has increased so rapidly and has been of such positive nature as to leave no doubt upon the subject in the minds of those at all open to conviction. This

evidence bears not only upon the pathogenic properties of the bacillus in question, but upon its occurrence as well, so that it is now possible to assert that it not only occurs in diphtheria, but that it does not occur elsewhere as a factor in any other pathological change, and that, grown under artificial conditions in pure culture, it will, upon inoculation in pure culture in susceptible animals, produce a change in all respects resembling that from which it originally came; so that the complete chain of evidence connecting this organism with diphtheria as a causal factor is before us.

The second point, and quite as important as the first for our purposes, is this: That there occur, not infrequently, processes that do not differ clinically in any perceptible degree from those produced by the bacillus of diphtheria, that can not be distinguished from diphtheria by any ordinary means of observation, and that, nevertheless, are not diphtheria and have not the dangerous character of this disease, either for the one afflicted or for those exposed to the infection from it.

This is the gist of the whole matter, and its great importance will, I think, be very readily apparent, for if a patient be not affected with diphtheria, he should certainly not be exposed to the disease by being sent into a diphtheria ward, and vice versa, if he has diphtheria, even in so mild a form that the clinical diagnosis may be doubtful, he should not be allowed to escape a proper amount of isolation and care. That patients with clinical symptoms of diphtheria, but not really affected with it, are frequently unnecessarily exposed is sufficiently shown by numerous experiments. Martin (*Ann. de l'Inst. Pasteur*, 1892, p. 334), after the careful study of 200 cases sent to the diphtheria wards of the Children's Hospital in Paris, comes to the following conclusions, that the most expert clinician is deceived once in five times, either by considering a case diphtheria that is not so, or else by failing to recognize diphtheria when it is present. Koplik (*N. Y. Med. Journ.*, August 27, 1892) and Park (*N. Y. Med. Record*, July 30 and August 6, 1892) bear out this assertion by the results of their elaborate investigations, and many observations of a less extensive character tend invariably to show the same thing, the impossibility of making an absolute diagnosis of diphtheria, even when false membrane is present, by ordinary clinical observation.

As to how many cases of mild diphtheria, without false membrane, escape detection, there is but little evidence. This from the nature of the problem is perfectly natural, for mild cases of throat trouble do not come under hospital observation, and experimental evidence must be obtained, as a rule, from hospital material. But it is evident that these mild, unwatched cases may easily be the most dangerous as foci of infection, and that, if there be any means for detecting them, these means should be generally known and employed. It is the purpose of this paper to explain what these means are and of what service they may be.

The series of papers by Roux and Yersin (*Ann. de l'Inst. Past.* T. II., p. 629; T. III., p. 273; T. IV., p. 385) are classics and first called general attention to the subject; Welch and Abbott (*Bull. Johns Hopkins Hospital*, 1891), Tangl (*Arb. auf dem Gebiete der Path. Anat. und Bakt. aus dem Path. Institut zu Tübingen.* Bd. I., Hft., I., s. 85), Baginsky (*Berl. Klin. Woch.* 1892, No. 9), Barbier (*Rev. Mens des Maladies de l'Enfance*, November, 1892), Heubner (*Schmidt's Jahrbucher*, CCXXXVI, 1892), Booker (*Bull. Johns Hopkins Hospital*, 1892), and Neumann (*Deut. Med. Woch.* 1893, No. 9), all furnish recent and important evidence, both as regards the weight of the evidence to be obtained and the methods by which it is to be sought. The evidence is of course the proof of the existence or non-existence of the bacillus of diphtheria in any given case; the methods by which this is to be determined are by microscopic observation, and by culture upon appropriate nutrient media of material obtained from the suspected locality.

The characteristics of the bacillus of diphtheria, so far as they concern the point in question, are as follows: It is a rod, either straight or slightly curved, with rounded ends, and having a diameter of  $0.5$  to  $0.8\mu$  and from  $2$  to  $3\mu$  in length. Irreg-

ular forms are very common, and especially in an unfavorable culture medium, very great differences in form and dimension may be observed; one or both ends may appear swollen, or the central portion may be notably thicker than the extremities, or the rod may be made up of spherical or oval segments. Multiplication occurs by fission only and the bacilli do not grow out into filaments. In unstained preparations certain portions of the rod, and especially the extremities, are observed to be more highly refractive than the remainder, and in stained preparations these highly refractive parts are seen to be most deeply colored.

The diphtheria bacillus may be stained by the use of Löffler's alkaline methylene blue (sat. alc. sol. meth. blue, 30 parts., aq. sol caustic potash (1-10000) 100 parts), but is not so readily stained with some of the other aniline colors commonly employed. It stains also by Gram's method. "For the demonstration of the bacillus in sections of diphtheritic membrane nothing can surpass in brilliancy and sharp differentiation sections stained doubly by the modified Weigert's fibrin stain and picrocarmine" (Welch and Abbott). The diphtheria bacillus is aerobic, non-motile, and non-liquefying; it does not form spores. It grows most freely in the presence of oxygen, but is also a facultative, anaerobic organism. Development occurs in various culture media at a temperature of from 20°-42° C., the most favorable temperature being about 35° C. It grows rapidly in nutrient gelatine having a slightly alkaline reaction, in nutrient agar, glycerin agar, or in alkaline bouillon, but the most favorable medium appears to be the one first recommended by Löffler, viz, a mixture of three parts of blood serum with one part of bouillon added, the latter containing 1 per cent of peptone, 1 per cent of grape sugar, and one-half of 1 per cent of sodium chloride. This mixture is sterilized and solidified as is usual with blood serum. Upon it the development is so rapid in the incubating oven that at the end of twenty-four hours the large, round, elevated colonies of a grayish-white color and moist appearance may be easily recognized, while other associated bacteria will, as a rule, not yet have developed colonies sufficiently large to interfere with the recognition of these. (Sternberg's Bacteriology, p. 360.)

These are the facts in the case, not only that diphtheria is produced by a specific form of microörganism, but also that this microörganism is possessed of certain specific characteristics by means of which it may be isolated and identified in so short a time as to make this procedure of great value in the management of individual cases. The importance of carrying out the investigation lies in the fact that without it it is not possible to be certain of the diagnosis in single cases, as has been shown in every series that has been properly studied. The method by which this may be done that has been most commonly used is that of Roux and Yersin (Ann. de l'Institut Past. T., iv. p. 386) following Löffler (Mitt. a. d. Kais. Gesund., Bd. II) and consists of two parts, the microscopic and the culture examination. The examination by the microscope may be made as follows: A fragment of the false membrane is removed upon a tampon of absorbent cotton held in forceps or supported upon a handle of some kind. The membranous débris are pressed upon cover glasses in such a way that the part coming in contact with the cover glass shall be that from the false membrane and not the buccal surface. The covers dried and passed through the flame are colored, some with Löffler's methylene blue, and some with gentian violet and after Gram's method, then washed with water and examined, while still wet, with a homogeneous immersion lens. (Instead of Löffler's methylene blue, Roux and Yersin made use of a blue made up of dahlia violet and methyl green. This is prepared by mixing one part of a 1 per cent solution of violet in water with three parts of a 1 per cent watery solution of green, and adding enough water to make a clear deep blue. This color gives no precipitate and keeps for a long time. It is enough to put a drop of the stain upon the cover glass and then almost at once to place this upon the slide, soaking up the excess of stain with filter paper. The diphtheria bacilli are those that take up the stain most quickly and intensely.

Among all the other bacteria that may be present the diphtheria bacilli, not infrequently grouped together in little masses, appear as rods with ends somewhat narrowed and rounded, slightly curved, swollen in pear or club shape, granular, and irregularly stained. By Gram's method they are deeply stained. They are never absent in true diphtheria, and with a little practice they may be easily distinguished from the other bacteria. In certain severe cases they appear in almost pure culture, but ordinarily they are mixed with other varieties, although in looking over the preparations the little characteristic bunches of the rods may be seen. This procedure is extremely rapid and gives good results, but if one desires to establish the diagnosis as a matter of absolute certainty the bacillus must be isolated and pure cultures must be obtained. This can be done very easily and rapidly after Löffler's method by sowing the false membrane upon coagulated serum. This is so favorable a medium for the development of the diphtheria bacillus that the bacterium will show its characteristic colonies in less than twenty-four hours at 37° C., while the other bacteria have scarcely begun to develop. (The streptococcus, which is almost always present in false membranes, gives very small colonies upon serum, and these grow very slowly.) It is sufficient to break up the fragments of false membrane used for microscopic examination with a platinum spatula and to draw this over the surface of the serum two or three times in separate lines without recharging it. This spatula can be used for removing the material from the throat in the first place instead of the tampon of cotton. The false membrane should be gently scratched with it and it should then be drawn several times over the surface of the serum in several tubes. The tubes are then to be placed at a temperature of 37° C., and in less than twenty-four hours the diphtheria colonies can be clearly distinguished. They are round dull-white spots with a center darker than the periphery. They remain small in the first tubes, or part of the tube inoculated, because they are so crowded, but in those portions last sown they spread and increase in size, and in forty-eight hours have taken on a perfectly characteristic appearance.

The difference between tubes sown from true diphtheria and from cases simulating it is very marked after twenty-four hours at 37° C. In the former there appears a very large number of colonies all of precisely similar appearance and characteristics, while in the latter there very frequently occurs almost no growth at all. It is very rare that the other bacteria prevent the appearance of the characteristic diphtheria colonies. The colonies must be examined under the microscope as well, and must be shown to be made up of bacilli presenting the characteristics spoken of above. The more so because there is a micrococcus that presents colonies on serum at 37° C., after twenty-four hours, that answer in size and appearance to those of the true diphtheria bacillus, but which can, of course, be separated from them by the microscope. These cultures upon serum can also be very well made from dried false membrane, which can be softened in distilled water and then treated like fresh membranes, but much the better plan is to make the culture at the bedside, for in this way the chances of contamination are much diminished.

A source of error to be looked out for in this procedure is the occurrence of the pseudo-diphtheritic bacillus, an organism first described by Löffler himself, and which in its colonies and under the microscope resembles the true diphtheria bacillus so closely as to be indistinguishable from it. Its essential difference is that it is not pathogenic upon inoculation in pure culture, and as regards its interference with the rapid bacteriological diagnosis of diphtheria it may be disregarded. For, although it has been found to be widespread in the mouths of healthy children, nevertheless when it does occur it is present in very small numbers, so that the appearance of the tubes containing it is very different from that of those containing the numerous colonies of the true diphtheria bacillus. "In every case in which there is a notable number of colonies it can be concluded that diphtheria is present even before knowing the result of inoculations in animals; errors will be extremely rare." (Roux and Yersin., loc. cit., p. 413.)

For the reason that coagulated blood serum with the proper proportion of bouillon added is somewhat difficult to have continuously on hand, substitutes for this medium have been sought for in order to render the employment of this method of diagnosis more easy. It has been found impossible to suggest anything that is quite so good for the purpose as blood serum, but among the media that have been employed is egg albumin. This may be used, as suggested by Wyatt Johnston (*Phil. Med. News*, Dec. 10, 1892), by boiling an egg hard, which, of course, solidifies the albuminous contents and at the same time sterilizes the shell. There is prepared at the same time an ordinary egg cup, which may be sterilized by burning a little alcohol in its hollow. A small portion of the shell of the egg is then chipped off at one end, and a minute portion of material from the throat of the suspected case is drawn over it with a platinum needle in the same manner as before described. The egg is then inverted in the egg cup and the whole placed in a warm place over night. This, however, is but a modification of the method of using this material suggested by Sakharoff (*Ann. de l'Inst. Past.*, T. VI, 1892, No. 6), by which the eggs, after being boiled hard, are opened, the albumin is sliced in pieces of convenient size, placed in sterilized test tubes with a few drops of water to retain the moisture, and cultures are made upon the slices of solidified albumin in the same manner as upon blood serum.

This, then, is the manner in which the diagnosis may be made, the procedures necessary being the inoculation of a favorable nutrient medium with material from a suspected case and the keeping of these cultures at a temperature of 37° C. for twenty-four hours. The points in the diagnosis are the rapid growth of the colonies at this temperature, outstripping that of almost all other bacteria, the physical characteristics of these colonies thus grown, and the appearance, under the microscope, of the bacteria of which they are made up, as well as the behavior of these bacteria to the aniline colors.

I have had made a case that appears to me to fulfill the requirements of this method of diagnosis. It contains two test tubes with nutrient media, two glass rods with platinum needles inserted at one end, and a box for holding cover glasses. A pair of forceps was not included in the case, for it would have added to the expense, and forceps are to be found in every physician's bag, and can be used and sterilized and used again, if necessary, for a series of cases, while the case contains only what is necessary for a single case.

The importance of this method of diagnosis has been already recognized by the New York Board of Health, which has recently issued a circular calling attention to it and offering to carry it out in all cases, and the recent results reported show that by this test fully one-third of the cases sent to the Willard Parker Hospital were cases of false diphtheria, that is, did not show the diphtheria bacillus upon investigation (*N. Y. Med. Journ.*, Aug. 26, 1893).

The impossibility of separating croup and diphtheria, from an etiological point of view, is shown by such work as that of Concetti (*Arch. Italiano di Pediatria*, x, 1892), who failed to find the bacilli only twice in sixteen cases of croup examined. Escherich (*Cent. f. Bakt. Bd.* VII, s. 8), Wurtz, and Bourges (*Cent. f. Bakt. Bd.* VIII, s. 301), and lately Welch and Councilman (*Trans. Mass. Med. Soc.* 1893), seem to show that, in certain cases at least, the inflammations of the throat occurring in scarlet fever are of diphtheritic origin. Baginsky (*Arch. f. Kinderheilkunde*, Bd. XIII, s. 418) examined 93 cases of suspected diphtheria, in 68 of which he found the bacillus of diphtheria. Among these 68 cases there were 27 deaths (40 per cent), while there was but 1 death in the 25 cases in which the bacillus was not found, and this point of the far greater mortality from true diphtheria than from false has been emphasized by many others as well. He also lays stress upon the diagnosis in what he calls "scarlatinal diphtheria."

Tobiesen (*Cent. f. Bakt. Bd.* XII, 1892, No. 17) attempted to determine the length of time that the bacillus of diphtheria would persist in the throats of convalescents,

and found it in 24 cases out of 46 examined for varying lengths of time, extending from four days to, in one instance, thirty-one days after the swelling had gone. With cultures from 19 out of these 24 cases inoculation experiments were made, with positive results in all of them, thus proving the continued virulence of the organism. These references, with many others that might be made, show with great distinctness the problems that can be settled in cases of suspected diphtheria by bacteriological examination, but the especial point that it has been my desire to emphasize before such an audience as this is the value of the procedure for diagnostic use.

## SUR LA MALARIA CHEZ LES ENFANTS A RIO DE JANEIRO.

Par le Docteur MONCORVO,

*Membre correspondant de l'Académie de Médecine de Paris.*

Aussitôt que je me suis consacré à l'étude et à la pratique de la clinique pédiatrique à Rio, je ne tardai guère à me rendre compte de la remarquable fréquence de la malaria au milieu des diverses entités morbides dont y sont affectés les enfants de tout âge. Elle est à coup sûr, après la syphilis héréditaire, la maladie prédominante dans le tableau de notre pathologie infantile.

Les quelques remarques qui vont suivre à son propos ont pour base un stock d'environ 5,000 cas de malaria aiguë, sub-aiguë ou chronique observés chez des sujets appartenant à toutes les périodes de l'enfance.

Pour donner une idée de sa fréquence il me suffira de reproduire ici le relevé statistique des faits de cette nature enregistrés dans mon service au cours des deux dernières années (1891-1892).

|                      | 1891. | 1892. | Total. |
|----------------------|-------|-------|--------|
| Total des cas .....  | 633   | 765   | 1,398  |
| Cas de malaria ..... | 242   | 271   | 513    |

D'après ces chiffres la malaria se montre dans une proportion de 36 pour cent environ, par rapport aux autres maladies de l'enfance.

En envisageant ces 513 cas de malaria d'après la période de l'enfance où ils ont fait leur apparition, on les trouvera répartis de la façon suivante:

|                        | 1891. | 1892. | Total. |
|------------------------|-------|-------|--------|
| De 0 à 3 mois .....    | 37    | 41    | 78     |
| De 3 mois à 1 an ..... | 55    | 65    | 120    |
| De 1 à 2 ans .....     | 56    | 62    | 118    |
| De 2 à 7 ans .....     | 52    | 76    | 128    |
| De 7 à 15 ans .....    | 42    | 27    | 69     |
| Total .....            | 242   | 271   | 513    |

Il en ressort ainsi la prédilection marquée de la malaria pour la première année de la vie; au fait, sur les 513 cas recueillis au cours de deux années, on compte 198 observés pendant cette époque de l'enfance, soit environ 35 pour cent.

Vient en deuxième rang la période comprise entre 2 et 7 ans, soit 25 pour cent sur le total des cas.

Comment expliquer cette prédominance du mal chez les sujets du premier âge? Tiendra-t-elle au vice du régime alimentaire?

Le relevé statistique des cas où on a pu enregistrer le genre d'allaitement m'a permis de dresser sous ce rapport le tableau suivant :

|                             | 1891. | 1892. | Total. |
|-----------------------------|-------|-------|--------|
| Allaitement maternel .....  | 79    | 104   | 183    |
| Allaitement artificiel..... | 54    | 49    | 103    |
| Allaitement mixte.....      | 53    | 16    | 69     |

Il est facile de voir après cela qu'il n'y a guère lieu d'incriminer les écarts du régime comme étant la condition primordiale de la plus grande réceptivité des petits sujets. Il va sans dire que toute entrave à la nutrition, quelle que soit son origine, ajoutée à l'état encore rudimentaire de l'organisme infantile, ne pourra manquer de le prédisposer à tout genre d'infections.

L'activité exagérée des voies d'absorption à cette phase de la vie semble contribuer pour une plus large part à la pénétration du germe malarien.

Une condition particulière de la composition du suc gastrique des jeunes enfants, notamment des nouveau-nés, paraît agir conjointement pour leur plus grande réceptivité à la malaria.

Mes recherches publiées, en 1889, au sujet de la sécrétion gastrique des petits sujets montrent en effet que de la naissance à la fin de la deuxième année l'insuffisance gastrique est presque invariablement due au déficit ou à l'absence de l'acide libre du suc gastrique.

On connaît bien aujourd'hui la faculté que possède le suc gastrique normal de détruire ou d'atténuer la virulence des germes introduits dans la cavité stomacale. Cette composition encore imparfaite du suc gastrique des jeunes sujets les prive de la sorte de ce moyen défensif si utile chez les adultes à l'état sain.

D'ailleurs, l'aptitude des petits enfants aux refroidissements d'une part, et l'activité sécrétoire exagérée de leurs glandes sudorales pendant nos longues saisons estivales d'autre part, concourent à en augmenter la prédisposition à contracter la malaria.

Les dystrophies héréditaires en amenant l'abaissement de la résistance organique ne laissent pas moins de jouer un rôle assez important par rapport à l'accroissement de cette réceptivité. D'après mes observations, la syphilis y figure au premier rang; c'est ainsi que sur un total de 513 enfants atteints de malaria on retrouve chez 209 les signes avérés de la vérole congénitale, ce qui donne une proportion de 39 pour cent.

C'est à peine si dix de ces enfants portaient conjointement des traces de tuberculose. Il découle en somme de mes observations personnelles que les sujets du premier âge présentent une bien plus grande aptitude à contracter la malaria que ceux ayant dépassé cette période de l'enfance, ce qui est d'accord avec l'observation de presque tous les pédiatres, encore même de ceux qui exercent aux climats absolument différents du nôtre.

Il n'y a rien de particulier à dire en ce qui regarde le sexe. Au fait, sur les 513 cas de malaria, 274 appartenaient au sexe masculin, 239 au sexe féminin, ce qui donne au premier une médiocre majorité de 35 cas.

En ce qui concerne les races les cas en question se répartissent comme il suit :

|              | 1891. | 1892. | Total. |
|--------------|-------|-------|--------|
| Blancs.....  | 159   | 187   | 346    |
| Métis.....   | 61    | 64    | 125    |
| Nègres ..... | 22    | 20    | 42     |
| Total.....   | 242   | 271   | 513    |

Ces chiffres qui expriment à peu près la moyenne de mon stock d'observations de malaria semblent indiquer un certain degré d'immunité des enfants de race noire pour cette sorte d'infection.

Il paraît qu'on n'avait songé jusqu'ici à la rechercher.

La presque totalité des petits malades compris dans mon relevé était nés à Rio ou en d'autres villes du pays; 482 étaient en effet brésiliens, 14 portugais, 14 espagnols et 3 argentins.

Ils se trouvent d'ailleurs ainsi partagés par rapport à leurs habitations:

|                                               | 1891. | 1892. | Total. |
|-----------------------------------------------|-------|-------|--------|
| Cité commerciale.....                         | 81    | 54    | 135    |
| Faubourgs et quartiers ouvriers .....         | 103   | 161   | 264    |
| Quartiers environnant la partie centrale..... | 58    | 56    | 114    |
| Total.....                                    | 242   | 271   | 513    |

On voit d'après cela que la classe moins aisée de Rio fournit le plus grand contingent d'enfants atteints de malaria.

Mes 513 cas de malaria infantile se montrèrent au cours des différents mois dans la proportion qui suit:

|              | 1891. | 1892. | Total. |                | 1891. | 1892. | Total. |
|--------------|-------|-------|--------|----------------|-------|-------|--------|
| Janvier..... | 25    | 23    | 48     | Août.....      | 12    | 32    | 44     |
| Février..... | 31    | 28    | 59     | Septembre..... | 10    | 24    | 34     |
| Mars.....    | 34    | 32    | 66     | Octobre.....   | 19    | 27    | 46     |
| Avril.....   | 29    | 12    | 41     | Novembre.....  | 14    | 19    | 33     |
| Mai.....     | 20    | 23    | 43     | Décembre.....  | 22    | 17    | 39     |
| Juin.....    | 10    | 18    | 28     |                |       |       |        |
| Juillet..... | 16    | 16    | 32     | Total.....     | 242   | 271   | 513    |

Ces chiffres démontrent la plus forte proportion des cas pendant les trois premiers mois de chaque année, c'est-à-dire ceux les plus chauds de notre saison d'été, le mois de mars étant celui qui fournit le contingent le plus élevé.

On y voit par contre baisser à 60 le chiffre des cas au cours des mois de juin et juillet, ceux précisément les plus froids de notre courte saison d'hiver.

La hausse ou la baisse de la chaleur atmosphérique exercent donc une influence indéniable sur l'accroissement ou la rareté des faits de cette nature au tableau de la pathologie infantile à Rio.

J'ajouterai ensuite quelques remarques concernant les allures particulières que revêt la malaria chez les jeunes sujets.

D'une façon générale: invasion insidieuse, notamment chez les nouveau-nés; symptômes initiaux vagues, mal définis, restant souvent inaperçus aux yeux des parents; agitation nocturne, insomnie, soif, refroidissement plus ou moins accusé des extrémités, pâleur du visage, des pleurs fréquents sans motif apparent, parfois encore une transpiration générale ou partielle (notamment à la tête).

A côté de ces manifestations à peu près banales, il est très commun de voir un changement de l'aspect et de la composition des selles, lesquelles se répètent tout en devenant grumelleuses, verdâtres, panachées, sereuses ou séro-bilieuses, d'une odeur acide ou fétide.

Elles sont alors presque souvent précédées, accompagnées ou suivies de coliques, parfois d'une très vive intensité, de même que du ballonnement du ventre.

Lorsque le petit patient n'a point encore atteint l'époque probable de la dentition pour qu'on pense à lui rattacher cette diarrhée, ses parents n'hésitent presque jamais à la rapporter à quelque cause d'ordre alimentaire, encore même que l'enfant soit nourri au sein par sa mère ou par une bonne nourrice.

Le petit malade maigrit à vue d'œil, pâlit davantage, devient très grognon, en même temps que la chaleur fébrile s'élève alors suffisamment pour attirer l'attention des personnes de son entourage.

La fièvre revêt presque souvent dans ces cas un type rémittent des plus irréguliers, entremêlé parfois de courtes intermittences dont les maxima varient toujours, ce qui m'a fait qualifier dès longtemps d'anarchique le type de la fièvre malarienne dans l'enfance et plus particulièrement chez les nouveau-nés.

Si le mal n'est point entravé de suite, ou si on ne lui oppose qu'une défense médiocre, on ne tarde guère de voir la situation de plus en plus s'aggraver; les traits de l'enfant s'altèrent, la soif augmente, l'intolérance gastrique se déclare, la diurèse diminue, l'agitation s'accroît progressivement, bref des convulsions éclatent et le dénouement fatal ne se fait pas attendre. L'acuité de la marche ainsi que la gravité menaçante de l'empoisonnement malarien deviennent moins redoutables au fur et à mesure que l'enfant s'éloigne du premier âge, mais ce début obscur, d'une bénignité souvent trompeuse, l'anarchie du cycle fébrile, cette banalité des manifestations initiales ne laissent pas moins de constituer aussi en quelque sorte les traits caractéristiques de l'empoisonnement malarien chez les enfants ayant déjà dépassé la deuxième année.

Les symptômes nerveux, d'une exceptionnelle gravité au cours de la première année, deviennent graduellement moins fréquents et moins dangereux chez les enfants plus avancés en âge.

Les complications cérébro-médullaires, méningitiques broncho-pulmonaires, gastro-intestinales, rénales, isolées ou combinées, viennent très souvent obscurcir au plus haut degré les signes propres à l'empoisonnement primitif.

Ces localisations viscérales, qui d'après nos connaissances bactériologiques actuelles ne sont autres que le résultat d'une infection secondaire, m'avaient conduit à établir plusieurs formes cliniques de la fièvre malarienne telles que: forme cérébrale, méningitique, médullaire, gastro-intestinale, rénale, etc.

Autour de ces types principaux se groupent les formes larvées, d'une fréquence peut-être plus grande chez les jeunes sujets qu'à l'âge adulte.

Leur description détaillée prendrait ici trop de place; la syncope, le vertige, l'étourdissement, la céphalée, le sommeil, la dyspnée d'origine centrale, la tachycardie, les points de côté, les gastralgies, les vomissements, les entéralgies, les hépatalgies, les splénalgies, les cystalgies, les polyuries, les spasmes vésicaux, etc., voilà autant de phénomènes qui s'imposent par leur intensité ou par les souffrances qu'ils amènent.

Il est bien à remarquer que chez les enfants, notamment chez ceux du premier âge, l'accès de fièvre malarienne ne se compose, ainsi qu'il arrive à l'âge adulte, des trois stades de frisson, chaleur et sueur. Le frisson fait toujours défaut chez les premiers; à sa place il y a presque souvent lieu de constater l'hypothermie périphérique ou, dans quelques cas plus rares, le refroidissement général de la surface cutanée accompagnée de sueurs froides et d'adynamie. Dans d'autres cas l'accès débute par l'élévation de la chaleur, la peau restant jusqu'à la fin absolument sèche. Le stade de sueur qui peut précéder ou suivre l'accroissement de la chaleur constitue parfois la seule manifestation de l'accès.

Les accès prennent donc dans l'enfance des allures spéciales qu'il faut bien connaître pour éviter des méprises fâcheuses. Une autre particularité aussi digne de note est l'absence fréquente, dans le jeune âge, de l'hyperémie hépatique et plus souvent encore de celle de la rate. Il faut toujours compter sur cette variabilité séméiologique, sur cette véritable anarchie de types et de formes que revêt la malaria aiguë à cette époque de la vie.

La déchéance organique en est la conséquence immédiate, elle se traduit par l'amaigrissement et par la perte du poids. En pesant presque souvent mes petits malariens j'ai été ainsi à même de les voir perdre de 100 à 500 grammes dans l'espace d'une semaine.

L'examen des urines dénonce souvent chez eux la présence de peptone de même que le taux des phosphates et des urates au-dessus de la moyenne normale. Dans quelques cas moins fréquents l'albumine s'y montre dans des proportions variables. Jamais il ne m'a été donné d'y retrouver la présence de glycose.

Les formes chroniques, apyrétiques se traduisent plus particulièrement par le ralentissement de la nutrition, par l'anémie, par la dyspepsie, la dilatation de l'estomac, la diarrhée lientérique, l'hypertrophie de la rate ou du foie, isolés ou associés, par le changement du caractère, l'état nerveux, l'insomnie, le retardement intellectuel. Parfois, l'organisme de l'enfant arrive à un degré extrême de dystrophie, que j'ai désignée sous le nom de phthisie malarienne.

Il est très commun alors de voir la maigreur squelettique du thorax et des membres contraster sensiblement avec le ballonnement considérable du ventre, ce qui les rend comparables en apparence aux petits sujets atteints de carreau.

Cette ressemblance a donné souvent lieu à des regrettables erreurs de diagnostic, ainsi que je l'ai à plusieurs reprises signalé dans mes cliniques. L'examen du sang dans le but de découvrir les hématozoaires de Laveran, souvent répété par Moncorvo fils, chargé des travaux bactériologiques dans mon laboratoire, n'ont donné jusqu'ici des résultats satisfaisants, nonobstant l'emploi rigoureux de la technique adoptée par Laveran, Romanowsky, Roux et Gram.

Le diagnostic de la malaria n'est point toujours facile. Chez les jeunes sujets l'intoxication se prête souvent à la confusion avec les formes aiguës de la tuberculose. L'embarras augmente davantage lorsque les deux états morbides coexistent, ce qui n'est pas rare chez nous.

Il faut toujours se méfier de tout état morbide mal défini qu'on ne puisse rattacher à une cause bien avérée.

La malaria restant souvent latente pendant un temps indéterminé peut éclater sous l'influence de causes les plus diverses; une chute, une vive émotion, la peur, un refroidissement, un traumatisme, une opération chirurgicale, ou enfin l'invasion d'une autre maladie infectieuse, telle que la rougeole, la scarlatine, la variole, etc.

C'est pour cela que je ne cesse de répéter à mes élèves ce précepte dont ils doivent tenir toujours compte. Méfiez-vous toujours de la malaria auprès d'un enfant malade à Rio; et j'ajouterai qu'il faut dans quelques cas la soupçonner car elle se cache parfois à nos moyens ordinaires pour la découvrir.

Pour que la gravité de la malaria dépasse toujours celle des autres âges, il ne faut jamais oublier qu'une intervention thérapeutique puissante venue à temps peut triompher des cas paraissant même au-dessus des ressources de l'art.

Il faut que le mal soit reconnu à son début et que la thérapeutique agisse de suite avec l'activité et l'énergie désirables.

La quinine doit être donc administrée à des doses proportionnelles à la gravité du cas et pas exclusivement à l'âge du petit malade.

L'organisme infantil tolère bien mieux la quinine que celui des adultes; l'activité de ses émonctoires, notamment de l'appareil rénal, en facilite beaucoup l'élimination.

Son amertume la rend pourtant d'une administration peu commode par la voie gastrique; les enfants la rejettent facilement en faisant perdre de la sorte un temps précieux.

Il ne faut compter d'autre part sur son introduction par la voie rectale, les lavements étant fort mal supportés par ceux-là.

Il y a encore des médecins qui recourent aux frictions cutanées d'une pommade ou d'une solution vinaigrée ou alcoolique d'un sel de quinine.

C'est là une méthode infidèle qui aurait dû être abandonnée dès que Briquet a suffisamment démontré, par des expériences jamais contestées, que l'absorption de la quinine est à peu près nulle par la voie cutanée.

Celle la plus sûre, notamment lorsque le cas est pressant, c'est sans contredit la voie hypodermique. J'ai été le premier à l'introduire dès 1874 dans la thérapeutique infantile.

Je me servai d'abord pour cela du sulfate basique de quinine dissous à l'aide de l'acide tartrique. Plus tard je m'adressai de préférence au bisulfate; enfin depuis ces dernières années je me suis arrêté au bichlorhydrate de quinine, celui-ci renfermant la plus forte proportion d'alcaloïde tout en étant d'ailleurs d'une extrême solubilité.

En m'entourant des plus rigoureuses précautions aseptiques je pratique à une très vaste échelle les injections hypodermiques de quinine sans en observer des accidents; j'introduis profondément la canule jusqu'à la surface musculaire, en rendant de la sorte moins douloureuse la pénétration du liquide injecté qui est d'ailleurs plus activement absorbé.

Les régions préférées sont la rétro-trochantérienne et l'inter-scapulaire.

Les doses varient, d'après l'intensité de l'infection, de 25 centigrammes jusqu'à 3 et 4 grammes dans la journée.

Lorsque je parviens à l'administration de doses quelque peu élevées de quinine, j'en neutralise l'action dépressive au moyen de la caféine que j'introduisis, dès 1888, dans la thérapeutique infantile, en l'employant par la voie hypodermique.

Elle agit comme un stimulant du système nerveux central tout en activant favorablement la sécrétion rénale.

Par son action tonique du cœur elle prévient les accidents à redouter du côté de cet organe lorsqu'une hyperthermie prolongée en menace l'intégrité anatomique et fonctionnelle.

Je viens tout dernièrement de communiquer à la Société de Thérapeutique de Paris un extrait de mes recherches sur le traitement de la malaria infantile, par une plante de la famille des synantherées, *l'helianthus annuus* ou tourne-sol.

La teinture alcoolique et l'extrait des diverses parties de la plante essayés sur plus d'une centaine d'enfants m'ont fourni jusqu'ici des résultats assez encourageants.

Le bleu de méthylène que j'essaye depuis l'année dernière, à la dose journalière de 15 à 40 centigrammes, mérite aussi d'attirer l'attention des pédiatres.

A côté de sa parfaite innocuité m'a-t-il donné déjà des résultats assez satisfaisants. *L'helianthus annuus* ainsi que le bleu de méthylène peuvent être bien profités pour les cas moins graves, sa saveur presque nulle rendant plus facile leur administration aux petits sujets.

Le traitement actif maintenu sans relâche parvient très souvent à triompher des cas les plus redoutables; cela dépend de son opportunité, laquelle suppose du reste un diagnostic porté sans le moindre retard.

Cette grande énergie d'action explique peut-être la mortalité absolument exceptionnelle dans mon service, où on a enregistré 14 décès par malaria en 1891, et 8 en 1892, au total 22, soit la proportion minime de 4 pour cent.

## PHYSICAL TRAINING OF SCHOOL CHILDREN.

By J. GARDINER SMITH, of New York.

The members of this congress, and especially of this section, have to do largely with individuals of school age. The school boys and school girls represent a large proportion of our respective communities. Whatever contributes to their welfare in mind or body appeals at once to our interest. Strong, healthy, educated men and women the world needs to-day and our meeting is to discuss ways and means of accomplishing this end. Therefore this topic is recognized by this body. We have to deal with these children through boards of education or private corporations, which in many towns are slow to believe in the necessity of the expenditure attending properly conducted physical training. To accomplish much we must urge progressive measures through the board of health or otherwise for the betterment of the bodily training of these children. The need is apparent. Scholars are taught words and facts and figures; their cerebral centers engorged with blood at the

expense of bodily growth and development. Teachers wonder why the young mind does not show more energy, why it does not grasp and retain and digest all this mental food. The fact is forgotten that the voluntary muscles contain perhaps one-fourth of the blood in the body and that through their activity a large proportion of the potential energy of the body is changed into work and heat. Springtime comes, and the pale face indicates the lack of recreative muscular exertion. (At this time the term malaria covers a multitude of sins of ignorance.) Such exertion is needed not alone to stimulate the growth of muscle, but to set free that energy which stimulates the growth of the mind.

As a pedagogic measure, physical exercise, properly directed, is decidedly important. One need but observe the standing or sitting position of school children, their awkward gait, difficult breathing when singing or speaking, to appreciate this fact. Kindergarten for the very young and manual training for older scholars aims to give the child better control of the muscles, more acute perception and judgment of external objects, besides practical knowledge. Now the main effects of exercise upon a single muscle (as Dr. Hartwell remarks in Hare's Therapeutics) are growth or increase in size and probably number of its structural elements, increased facility in its functional activity, and better response to central nervous stimuli. Secondly, kindergarten and manual training, to a limited extent, effect both muscle and mind. But the need to-day is a definite system of physical training which, by graded and more or less intricate exercises shall not merely develop muscle, but educate the mind to control and coördinate the whole voluntary muscular system. For, as Dr. Keating says in his Cyclopædia of Children's Diseases, "every movement of the body depends as much upon the proper coördination of the muscles for its accuracy, grace, and force, as upon the strength of their contraction."

The need of physical training as a hygienic measure is more imperative or at least more apparent. During the past two years I have examined upward of 2,000 public school children. A large proportion stood with abdomen protruding, shoulders and neck forward. The average expansion of the chest at the nipple was, boys, 1.1 inches; girls, 0.9 inch. The breathing was sufficient to support life, but the quantity of complemental and reserve air was very small. Very few could distinguish between diaphragmatic and costal breathing. About 10 per cent had an apparent scoliosis. Comparatively few rachitic children were found. Nearly all were right-handed. The step in most cases was fairly good, as the children had already been trained in marching.

After eight months of training, boy's chest expansion averaged 1.9 inches, a gain of 0.8 inch, and girls averaged 1.8 inches, a gain of 0.9 inch. Scoliosis had improved in 80 per cent of the cases. These examinations showed a most urgent need of training in the sitting and standing position, in development of muscles of trunk and upper extremities, and especially in the carriage of the body and mobility of the chest. It is well known that the circumference of the chest, together with the height and weight are factors that determine the capacity of the individual for military, naval, and other public duties. The chest expansion of boys and girls differs less in early years than later, largely on account of dress. Their bodies can be moulded and their proportions changed between 5 and 15 years as at no other. For all these reasons and many more, it is highly imperative that a rational system of physical training be pursued during these ages. Such a system should meet the demands—hygienic, educational, and recreative.

*Question.*—The practical question now arises, as to the method and its adaptation. Shall the system be German or Swedish, or what? Shall the teachers be alopaths or homœopaths, or what? I say let the system be American, comprising the best of all known exercises. Let the teachers be "regulars," well informed upon all the so-called systems, thoroughly familiar with the human body, able to examine the scholars and adapt the exercises to their needs. Too much time is spent to-day discussing systems, and too little in the study of needs and how to meet them.

Professor Ling compiled some exercises for the sick, and now the Swedes have an elaborate arbitrary system of exercises for sick and well. Father Jahn introduced some exercises to make better soldiers, and now the German Turners are known far and wide. M. Delsarte outlined a series of exercises for expression in oratory. His idea never was a system of gymnastics and should not be so construed. The colleges and Young Men's Christian Associations have adhered to no special so called system. What then should be the system of physical training of children in our schools?

*Method.*—As to the method, it must vary in detail according to circumstances. We must consider the condition and needs of the children first. This may be done by some form of physical examination. The heart, the lungs, the thoracic cavity, the condition of bones, of trunk, and limbs, the strength and development of the voluntary muscles should be noted and considered. Measurements of height, weight, chest, abdomen, hips, arms, and other important notes should be recorded. In this way the director of this department is enabled to place the children in proper classes, and to arrange and adapt the work intelligently. On the other hand, the children are thus stimulated to work for their physical improvement, and not merely to learn and perform certain mechanical exercises, with no definite end in view. Next we must consider the building, the room or rooms to be used, the number of teachers and number of grades, the length of time spent in each grade, the sex of the grades, the apparatus available. Next we must consider the mental capabilities of the children and suit the exercises to the various grades from this standpoint also. The system must be progressive from the A B C to the graduate who enters college or business. In this progression, however, fun and recreation should always be prevalent. The demands of hygiene, education, and recreation should underline the whole system. There are two other very practical considerations: first, the coöperation of the regular teachers, and second, the financial outlay. This latter need not be very extensive, although it should be sufficient to secure the best talent and best effort. One competent man with coöperation of the regular teachers might have the oversight of from 5,000 to 20,000 pupils, or with special assistants he might direct an almost unlimited work. I have been agreeably surprised to see the unanimous and hearty way in which principals and teachers have supported physical training in the schools of New York City.

With these facts before us we proceed to a more definite outline of exercises. Those permissible in school may be classified as follows:

For all, training in sitting position; training in standing position; breathing—upper thoracic, lower thoracic, diaphragmatic; marching, walking, running, hopping, skipping, jumping.

Lower grades, calisthenic exercises (innumerable) without apparatus.

Middle and upper grades, gymnastic exercises with apparatus, rings, dumb-bells, wands, Indian clubs, poles, bell bar.

Upper grade, heavy gymnastic exercises; horse, buck, parallel bar, horizontal bar, vaulting, jumping, ladders, rings, etc.

For all, games indoors and out. Innumerable games, especially in spring and fall, with much of the other exercise can be done and should be done out of doors.

It is not necessary to go into much detail regarding this classification, but some explanation may be profitable.

Assuming that we have a room well ventilated, with 200 cubic feet of air space for each individual and the most modern adjustable desks and seats, there are innumerable groups of enjoyable exercise which might be done by the children as often as every half hour at least. Motion is one of the means of rest to the growing child. He should not be restrained in one position longer than five or ten minutes. Neither should faulty positions tending to scoliosis and other deformities be permitted. Exercises in the sitting position may be alternated with risings, and facings, and marchings at intervals. This rest and recreation for body and mind need not be longer than one minute or two, or perhaps five.

*Standing.*—Before children are taught to march they should be taught to stand in the position of the soldier (see Revised Tactics, U. S. Army). Ask the untrained child to sit or stand erect and you will observe the shoulders thrown backward, head tipped back, and abdomen protruded in many if not all cases. Considerable training will be necessary to properly "set up" the child.

*Breathing.*—Perhaps the next most important point is control of the thoracic muscles, both for the health of the child and to improve his singing and speaking. He should be taught to use upper and lower thorax and diaphragm at once and each separately. These ideas inculcated into the minds of children might do much to inaugurate dress reform, because the child could see the impossibility of sufficient chest expansion with the chest constricted.

*Marching.*—Many evolutions in accordance with the United States Army tactics will prove interesting and beneficial to the scholar and to the school and will give us better men and women and better soldiers.

*Calisthenics.*—This field is almost unlimited where large, airy rooms are at command. In many schoolhouses calisthenics must be limited to such as can be done in a class room full of desks. It must be remembered, as Dr. Lincoln remarks in his article on school hygiene in Dr. Keating's Cyclopædia, "Above the age of 12 scholars begin to look down on free or calisthenic exercises as childish, and with good reason, for they lack one essential element, they do not call for exertion to overcome resistance. For better work scholars should have light dumb-bells, wands," etc. I would note another lacking element, viz, the recreation afforded by the fact of some apparatus held in the hand and used in the exercise. We see this desire for apparatus before the child reaches 12 years, and in New York City five primary grades use light apparatus. Calisthenic exercises may be grouped in drills for assembly or class room or gymnasium, occupying from one to twenty minutes. The progression proposed by Professor Ling, the grace and ease of expression as taught by Delsarte, and the recreative "rounds" of the Germans can be made exceedingly attractive when adopted to the needs of the scholars. The United States Army "setting up" drill, arranged to 4-4 time, has proved a very interesting and attractive assembly and class room drill.

Light gymnastic exercise (with apparatus) affords better opportunity to grade the exercise to suit the body and mind of the child of 5 and of 20 years; to cultivate not alone muscle, strength, grace, and agility, but to train the memory, perception, judgment, and almost every faculty of the mind, at the same time affording much recreation. Indian-club swinging, for instance, while simple and easy, can be made most intricate and interesting. This fact was illustrated at one of our New York school receptions, where the graduating girls gave a very creditable exhibition of club swinging, as shown in the grace of movement, complexity, and variety of exercise. The following is a classification of the graded drills used in New York City schools for the year ending June 30, 1893:

In grammar department: First grade, advanced Indian-club drill, No. 1; second grade, advanced bell-bar drill, No. 1; third grade, wood dumb-bell drill, No. 1; fourth grade, bell-bar drill No. 2; fifth grade, wood dumb-bell drill, No. 2; sixth grade, short-wand drill, No. 1; seventh grade, wood dumb-bell drill, No. 3; eighth grade, calisthenic dumb-bell drill, No. 4.

For the primary departments: First grade, Indian-club drill, No. 2; second grade, anvil-chorus dumb-bell drill; third grade, short-wand drill, No. 2; fourth grade, wood dumb-bell drill, No. 5; fifth grade, ring drill, No. 1; sixth grade, calisthenic drills, Nos. 1 and 2.

In the higher grades, where the ages range from 14 to 17 years, especially in the male department, heavy apparatus, such as horse, horizontal bar, etc., can be used to advantage. This work need not be limited to the boys' classes, though of course the work by the girls must be much simpler and easier of accomplishment. The element of resistance to exertion with this apparatus satisfies an evident demand and affords an increased amount of recreation. Here the class should work in squads

under competent leaders, who set the exercises and see that they are properly executed.

*Games.*—Of course the element of fun is greatest in the so-called "games." The rivalry and exertion completely changes the mental condition and recreates body and mind. These should not be carried to fatigue. Baseball, handball, basket ball, tag, etc., can be utilized in a most profitable way. Games will, I believe, hold a much more prominent place in the future than to-day in school-association and college gymnastics.

*How taught.*—In answer to this question we would say by the class teacher directly. Of course a director with medical and gymnastic training should outline and have the oversight of all this work. It does not necessarily follow that the teacher must in all cases be able to execute the exercise before the class, though this ought to be possible in most instances. If not there are always to be found natural leaders who will act under the teacher's direction. This plan has been followed in New York for two years with good results. The director of physical training should visit each school at intervals (perhaps once each week), reviewing the past work and setting some new exercises for each class. The exercises of each grade should be printed, and may be illustrated by photographs and placed in the hands of the teachers. The assembly work and marching orders will be about the same for all classes, but the grade work of course will vary in progression. When the exercises are well understood by the scholars, the piano or other music increases the interest and recreation of the work, and need be the only leader of the class. The exercises taught by the class teacher will prove mutually beneficial.

The reports of principals upon physical training in the New York City schools last year was universally favorable, and the demand there is for more money and more facilities for exercise. In Boston, Chicago, Kansas City, St. Louis, Washington, and a few other cities, physical training is being pursued with favorable report.

## CONTRIBUIÇÃO PARA O ESTUDO DOS CORRIMENTOS BLENNORRHAGICOS NA INFANCIA.

Por MONCORVO, FILHO.

*Assistente do Laboratorio de Biologia do Estado, Chefe de Clinica do Serviço de Pediatria da Policlínica do Rio, Membro effectivo do Gremio dos Internos dos Hospitaes, Bibliothecario do mesmo Gremio, Socio fundador da Sociedade Nacional de Acclimação, etc.*

D'entre os muitos casos clinicos interessantes, em que tenho baseado as minhas investigações bacteriologicas no serviço de pediatria do Prof. Moncorvo, alguns casos de blennorrhagia em crianças de pouca idade hão chamado particularmente a minha attenção.

Sete doentes de vulvo-vaginites blennorrhagicas, das quaes uma affectada de rheumatismo blennorrhagico e outras duas de conjunctivite tambem da mesma origem, foram de preferencia designadas pelo chefe do serviço para a confirmação microscopica. A idade d'estas doentes variava de 0 á 11 annos, notando-se que a doente de rheumatismo tinha apenas 2 annos e meio.

Para retirar dos doentes os elementos de estudo bacteriologico, usei sempre da mais rigorosa technica e asepsia.

Coloridas pela solução de Ziehl, todas as preparações deixaram ver, com pequena variante, abundantes nucleos do gonococcus de Weisser; ora achavam-se isolados, ora infiltravam os globulos de pús, sempre colorindo-se bem pela fuschina phenicada, a ponto de não deixar a menor duvida de sua abundante existencia.

Deixando de parte o interessante caso de rhennatismo blennorrhagico, convem lembrar o modo porque deu-se o contagio da blennorrhagia aos pequenos doentes. Tres haviam sido contagionados pelas proprias mães, que declararam achar-se, anteriormente a infecção de suas filhas, affectadas de abundante corrimento vaginal.

O caso que se refere ao rheumatismo tem sua origem da transmissão da blennorrhagia pela vehiculação do gonococcus por meio de uma bacia em que se lavava um tio materno da criança, affectado d'aquella molestia.

Os estudos microscopicos do sangue e do pus da abundante vulvo-vaginite d'este doente foram feitos repetidamente e com o maior zelo e vigor, em vista da importancia do caso, verificando sempre o gonococcus, que até consegui, como Criveli, cultivar em agar-agar peptonizado, e observar a forma adquirida pelo germen que proliferou no caldo. Esta forma era a mesma descripta por Peyer no seu Atlas de Microscopia Clinica.

Não tentei fazer inoculações em animaes porquanto sabe-se que a blennorrhagia só é transmissivel aos individuos da especie humana.

---

## THE RACE FACTOR IN DISEASE AS ILLUSTRATED BY PNEUMONIA IN THE NEGRO.

By J. WELLINGTON BYERS, M. D., of Charlotte, N. C.

Modern etiological investigation and study has succeeded in ascertaining and defining the exact scope and influence of a number of the most important contributory conditions and exciting causes of the acute zymotic diseases, though there still remains much to be learned and interpreted in bearing upon disorders of this class. In respect to the agencies of class, climate, age, sex, occupation, and habitation we already possess considerable accurate and valuable data. As regards the influence of the factor of race and nationality upon the advent and type of morbid phenomena we know as yet very little that is exhaustive and trustworthy, and there remains much to be recognized and understood. Up to this time, so far as I am aware, no one has made any systematic effort to determine the specialty of disease as it occurs in the various races of the world. This is true in the light of the fact that a number of disorders are far more formidable and lead exceptionally often to fatal results in the yellow and darker races as compared to the white. From an examination made of the mortality rates of the negro population of the Southern States of this country I have found in a number of instances that they were double that of the associated whites. In those communities where the population is a mixed one, possessing the negro contingent, this assertion can be easily verified by anyone who takes the pains to examine. Such being true, we find ourselves confronted with the solution of a grave problem connected with the welfare of a large number of people.

Is it possible, aside from the contributory agencies of age, sex, class, climate, and environment in general, that we have a distinct and measurable factor of race, and that one people should possess and manifest special proclivities to and exemptions from disease causes? In other words, is the unusual tendencies toward scrofula, consumption, and allied disorders shown by the Saxon people the effect of circumstances of life or of inherent racial traits? Are the Semitic people prone toward cancerous disease and melancholia and exempt from contagious disease to a degree evidencing almost a charmed life because of their habits of life, or by virtue of anatomical and corresponding physiological peculiarities of structure? In the light of data now available it is reasonable to conclude that the latter is true to some degree. Indeed it is fair to assume that all people of different stocks will differ as much physiologically as they do morphologically, yet it is very difficult in the absence of definite knowledge to demonstrate or affirm, in any particular case, how much of a supposed racial trait is due to original and inherent peculiarities and how much to the effect of circumstances of environment. There are considerable facts, however, to show, for some diseases at least, that variations are not due to fluctuations in environment. On the other hand, experiences show how potent the external conditions of existence are in determining disease. Every organism tends to

become adapted or acclimated to its conditions of life, and all the structures of a species, accustomed through countless generations to the climate, soil, food, and various other influences of a given locality, are molded into harmonious coöperation favorable to life in that locality, the result being that in the development of each young individual the tendencies conspire to produce a fit organism. It is otherwise when the species is removed to a habitat of different character. The Esquimaux will perish from consumption if removed to Copenhagen, although a few centuries ago he was of the same Scandinavian stock. In the transition the organs, partially out of harmony with the demands of the new life, become partially out of harmony with one another, and in this way the perturbed relations of the organs interfere with their original equilibrium and prepare the way for disease.

There are a number of diseases which illustrate the tyranny of organization and the influence of race, but the limits of this paper preclude their mention here. In the substantiation of the factor of race as an element in disease etiology I have selected a few statistics of the disease pneumonia. In investigating all of the available data pertaining to this disorder I have been impressed with the unusual susceptibility of the negro. In my practice among them in the South I have had occasion to notice the rapidity with which they pass into the apathetic and fatal condition. Many years since Austin Flint, in his work on practice, observed that "in sections of the Southern States pneumonia prevails at times sufficiently to be considered as endemic, and, affecting the negro population, often proves the scourge of the sugar and cotton planter." Reynolds's system says: "In certain sections, as in Sierra Leone, the Cape, and Mauritius, the negro race appears to suffer more than the whites." Hirsch, in his work on the geographical distribution of disease, says: "The same holds true in regard to the South American countries," and adds that "while immigrants from northern latitudes to subtropical or equatorial regions enjoy comparative exemption from inflammation of the lungs, the natives of the tropics, and most of all negroes, are subject to the malady in quite a peculiar degree, not merely when they go to colder climates, but also in their natural habitat." Pruner says: "The negro is excessively liable to pneumonia in Cayenne, and the malignancy of the disease is famous for its appalling fatality." Observers all admit of the fatality of this disease in Soudan, Zanzibar, and the west coast of Africa generally.

From the figures and citations it appears that the climate and situation has but little *per se* to do with the causation and results of this disease in the negro, and it matters little at what place or in what circumstances of climate or conditions of life he may be placed, he manifests a distinct and peculiar proclivity for this disease. Indeed, environments so potent in modifying and controlling the pathogenicity of many disorders of this class have but little effect in this one. Dr. Billings has noticed this, and in summing up his conclusions in regard to pneumonia as presented in the data of the tenth United States census, says, "The evidence furnished by the census does not favor the theory that this is a disease dependent upon climate or cold." The statistics of European countries also substantiate this, and we find pneumonia equally as prevalent and fatal in the southern section of Spain, Italy, France, and Greece as in Russia and Norway and Sweden. In all Europe the average death rate from this disease is the same as in the United States, being 15 for 1,000 population. In the States of Louisiana, Missouri, and Arkansas the mortality among the blacks reaches as high as 146 in each 1,000 deaths from all causes, the rate in the rural parts being as excessive as 152.8 and in the cities and in towns 111 for 1,000 deaths. The average rate of deaths among the whites in the United States is 108.88 and for the negro it is 142 for 1,000 deaths, being a difference of over 25 per cent. In pneumonia we know from experience that the factor of age is of itself sufficient to produce differences in the form or type of disease. In children we nearly always find the catarrhal or bronchial form, while in adults the lobar type is the rule. This holds true while the specific or germ factor remains the same in both. For an

explanation of this modification we must look to the coöperant conditions as found in differences in the structure of the lungs involved, and analogous conditions appear to hold good in regard to race. The foregoing figures point unmistakably to the conclusion that the colored race is more liable or susceptible to this disease. They are taken from a considerable portion of the territory of the earth, embracing almost every latitude, class, and condition:

As to what constitutes this special liability to the pathogenic agents of pneumonia and why it should prove so exceptionally fatal in this people science at this time does not furnish a satisfactory reply. The specific etiology and pathology has been very clearly determined, though wherein the particular defect of cell life or function or vital resistance exists is not understood, and I shall not attempt to speculate. In a general way we can conclude that there must be some defect of anatomical structure leading to corresponding defect of physiological competence in the tissues engaged in the struggle for existence between the cell and the germ of this disease. As to what this is and how it operates we do not know. My chief object in directing attention to this phase of etiology is to awaken interest in a much-neglected though vastly interesting and important field. As medicine becomes more scientific it must of necessity investigate all the facts concerned, and allot to each its importance in any given instance. In my contributions to Wood's Handbook and Keating's Cyclopædia I have dwelt at length upon certain phases of this subject, and have attempted to outline some of its bearings and indications.

## PROCEEDINGS.

The section meeting was at the Arlington Hotel, September 5, 1893, and was called to order by the executive president of the section, Julian J. Chisolm, M. D., LL. D., of Baltimore, Md., the English-speaking secretary, Dr. George M. Gould, of Philadelphia, being present as secretary. At this time or during the subsequent sessions the following members of the section were registered:

|                                               |                                            |
|-----------------------------------------------|--------------------------------------------|

| Dr. T. R. Wolfe, Glasgow, Scotland.           | Dr. F. M. Chisolm, Baltimore, Md.          |
| Dr. Arthur G. Hobbs, Atlanta, Ga.             | Dr. C. H. McConache, Baltimore, Md.        |

ADDRESS BY THE PRESIDENT OF THE SECTION, JULIAN J. CHISOLM,  
M. D., LL. D.

HONORED COLLEAGUES: It gives me much pleasure to have you participate in the Columbian festivities, of which the Pan-American Medical Congress is a part. Congresses, on various subjects pertaining to the sciences and the arts have been held at Chicago in commemoration of the discovery of America. When the doctors of this continent assemble in Washington it is only an extension of the general features of

this memorable anniversary. As surgeons we will assist, in our own way, to further the desire to make the year 1893 one to be long remembered in the history of our nation. Within the last few months there have been several gatherings of medical men; and yet we have our special mission. With medical advancement for our stimulating theme, we are anxious to help in the development of that great object, "The preservation of health," which is so closely allied to the creative power.

Every day the human race is becoming more aware that good eyesight is a most precious gift, and it is beginning to learn how to guard that gift zealously. Common school physiology has taught men that the healthy functioning of any organ of the body is not to know of its existence except through the comforts which it gives us. As soon as we are aware of its presence there is something wrong which requires correction. We, who are the special custodians of human eyesight, have come together to collate individual experiences and to put on record what we are doing in the way of maintaining the perfect working of this wonderful visual organ. In arranging the programme of work for the section I have deviated from the ordinary course of discussing promiscuous papers only, and have assigned two topics especially for our consideration, "Refractive errors, and muscle irregularities: How to detect and correct them." These two eye troubles comprise the heavy daily work of the ophthalmic surgeon. From the frequent appeals for relief the correction of these interferences with comfortable vision seem to be even more important to the masses of humanity than the great operations, when we restore sight to the blind by the most delicate of surgical manipulations.

I presume that my personal experience simply reflects the daily experience of each one of us, which is that refractive and muscle irregularities are as frequently met with as all the other eye affections put together. To have acute vision and not to be able to use the eyes with comfort is very worrying to thousands of people. To make painful eyes work smoothly and to remove head discomforts of long standing as if by magic, through the instrumentality of carefully adjusted spectacles, is a wonderful art, which is enthusiastically recognized by former sufferers. To effect this with certainty and with expedition is most desirable knowledge, and we are all seeking it. At the present time perfect relief is not always attainable. The majority of troublesome eyes adapt themselves promptly to the glasses which we adjust, and can be used painlessly when the proper spectacles are worn. But sometimes we meet with rebellious eyes, which our utmost care can not quiet; and yet we feel that these should also be brought under control. We try many ways to accomplish this desired object. Experience has taught each of us a method which we individually think is more convenient or more expeditious than the course pursued by others to secure the same end. Time is valuable to both surgeon and patient. All desire quickly to secure surely the best results. Our object is to study these individual methods. In refraction cases a very important question is when to use mydriatics, and to determine which of this class of remedies is the most reliable and least annoying. In our eager pursuit after the cause of the eye disturbance we must not forget that the patient also has some rights. To blur vision for a fortnight by atropine, if the same results can be secured by homatropine, which disturbs sight for only a few hours, is an abuse of professional power against a confiding patient, to whom every hour for labor may be needful to secure bread for the daily wants. We also desire to know to what extent we can be surely aided by apparatus, other than the trial case, to detect the kind and the degree of refractive error.

For many years we have been studying with diligence the faults in the eyeball itself, and how to help the ciliary muscle to accomplish its important work, often to the neglect of the much larger, more numerous extra ocular muscles, with equally important functions, to insure comfortable vision. We are only now waking up to the fact, too long overlooked, that the irregular action of these outer muscles fill a very conspicuous roll in causing eye discomforts. The want of equilibrium in their action must be recognized. The temporary or permanent use of prisms to strengthen

# EXPLANATION OF THE DIAGRAM.

Squares, males; circles, females; double-size squares or circles, for conspicuousness; black border, cases of hereditary optic atrophy; Roman numerals at side, the generation; small numerals above figures, children of the generation. Numerals in squares: *a*, if in black-bordered figure, age at which atrophy appeared; *b*, if with "D.", date of death; *c*, if alone, present age of patient; D. I., died in infancy; large squares or circles, with outline borders, are explained in the text.

DIAGRAM OF HEREDITARY OPTIC ATROPHY.

weak muscles, or the cutting of the over strong ones, are important problems for serious consideration. Complete or partial tenotomies is one of the questions of the hour.

To each of these subjects, which are now the leading ones in ophthalmic circles, we propose devoting an entire day, with the hope that so much knowledge will be elicited by the discussion as to enable us to define clearly rules for professional guidance.

---

## PAPERS READ BEFORE THE SECTION.

---

### HOMEOCHRONOUS\* HEREDITARY OPTIC-NERVE ATROPHY, EXTENDING THROUGH SIX GENERATIONS.

By GEORGE M. GOULD, A. M., M. D., of Philadelphia, Pa.,  
*Ophthalmologist to the Philadelphia Hospital.,*

The cases I herewith report are in several aspects unique, and in their suggestions and inferences are of most abundant interest. The diagram annexed shows fourteen or more instances of hereditary optic atrophy, scattered through six generations. The details will be made clear under the general aspects considered as follows:

#### PATHOGENY AND PATHOLOGY.

The earliest ancestor in whom, so far as ascertainable, the affliction appeared was a sea captain. All that I can learn about him is that he became blind and deaf somewhat late in life. His two sons became blind "from the same type of disease as that which has since appeared in the later generations." The hereditary nature of the affection is certain from the first generation downward. The primary cause, so far as I can see, is involved in complete mystery. The disease seems to be typical white atrophy of the optic nerve. In my patient the failure of vision was first noticed in March, 1892, and in nine months progressed to barely counting fingers. I have been able to get reports from hospitals, and other oculists who have examined other members of the family affected, and they all agree in the diagnosis.†

Macular vision is not so good in my patient as vision with a more peripheral portion of the retina. In a number of the cases the blindness is not absolute, but the patients have some slight vision that is retained through life.

The influence of sex in transmitting the malady is most marked and peculiar. In the entire series of histories there is not a pure or idiopathic instance of the appearance of the disease in a woman. In the third generation No. 3 had "weak eyes" and persistent "watering" of the eyes, but she was not blind. Her sister, No. 4, became blind before her death (at 40), but she was "horned in the temple by a cow and one eye thus destroyed," blindness following in the other eye a few months later. The remaining sister, No. 5, became blind late in life, from what cause I am unable to say. As none of her children were affected, I am inclined to think the cause must have been cataract and not optic atrophy.

But the most interesting phase of this subject consists in the remarkable fact that after the second generation no man transmits the affection to his descendants, and it is always transmitted by women who are unaffected. Passing the line through a male, even though he himself is blind with the disease, at once stops the appearance

---

\*Ομοιος, similar; χρόνος, time. Applied to a hereditary trait or disease, appearing at a similar age or time of life in a line of descendants.

†I am greatly indebted to Rev. T. M. Jackson, of Norristown, Pa., for his patient and scientific labor in gathering the details of the cases reported

of the disease. In this respect a similar law obtains in the hereditary transmission of hemophilia, which is often or largely through unaffected females. The same peculiarity has also been observed in idiopathic muscular atrophy, and I think cases of color-blindness have also been reported.

It is most noteworthy that in one group of my cases the inheritance is consecutively transmitted through two unaffected females, and in another group it is passed through three women.

There is one seeming or partial exception to the last law. In the fourth generation one man has a blind son, No. 4, who still lives at the age of 52. "While chipping something, a small piece flew in the eye; the injury was slight, but blindness resulted. The other eye is now partially blind and failing." This incident, together with others, and especially the histories of the three sisters in the third generation, show that normal vision or ocular health in the family was always on a precarious equilibrium, and when optic atrophy did not arise idiopathically only a slight accident or exciting circumstance was needed to bring on a train of evil results.

#### INGRAVESCENCE OF THE AFFECTION IN LATER GENERATIONS.

According to *apriori* expectation, and also according to other histories and hereditary laws, we should expect the disease to decrease in virulence with each intermixture of new blood, or with each marriage. But in the diagram we note that in the fourth generation there is but one example, while in the fifth there are six or seven. In the fifth generation there is but one woman who became a mother, and of her children I shall speak by and by. It seems clear that if there had been more mothers in the fifth generation there would have been a sad increase of blind men in the sixth generation. Did nature with subtle wisdom prevent this? It would also seem that the age at which the affliction appears is earlier with later generations.

#### IF NOT OPTIC ATROPHY, DEATH.

The proportion of early deaths has struck my attention. This begins to become manifest in the fourth generation. In the children of III-3 there are four deaths in infancy, in those of III-5 there are three, besides three or four deaths in early adult life—at about the age the optic atrophy appears in others. In the fifth generation all the males that live in one family are afflicted with blindness in early adult life, and the four other males born die in infancy. This virulence is to be connected with the fact that the line comes through a female. In the children of the second family the line passes through a male, and while the law is greatly modified, its power is shown by one death in infancy, and others at 28, 30, 35, 40, 46, and 48, with one case of blindness secondarily induced. In another family of this generation two males died in infancy, only one son surviving; in another, two sons died in early manhood, etc. The fathers of these transmit the line; but in the last case to be cited a mother is the medium, and of her four sons one dies in infancy and the other three are struck with blindness at 23, 28, and 34, respectively.

In the sixth generation, the only children who have a mother in this ancestral line are thus endowed: Three die in infancy; one, a girl, has a "weak mind;" one has optic atrophy at 27, and two younger brothers have chronically abnormal eye-grounds and optic-nerve heads.

Finally, it is suggestive to see that this law of extinction is probably now complete, or about to end. If my reading of the facts is correct, i. e., if only the female transmits the tragic inheritance, and only to males, there will, so far as I can learn, be no further cases, except possibly in the brothers of my patient VI-5. Every female of the line is now dead or childless. After discovering this law I was greatly anxious to see the brothers of my patient. With much difficulty I at last succeeded. My little scientific pleasure was immeasurably overbalanced by the sad ophthalmoscopic findings. In both there was a retina congested, stippled, and with chronic

degenerative changes taking place, an optic nerve unhealthy, without clear outlines, and hyperæmic—altogether a morbid fundus—though the young men have so far had no visual trouble. I shall watch the approach of the ominous age with much interest.

There still remains to note the great predominance of males in the later generations, a factor that tends to bring the vicious inheritance to a sharp ending. But the same purpose is outworked, and more manifestly by the rapid decrease of prolific females whose ancestral line descends through women unbroken by a male of the line. In the third generation, when the vicious tendency becomes manifest, there are two child-bearing females, a percentage to all children born of  $66\frac{2}{3}$ . In the fourth generation the percentage is less than three, and in the sixth generation it is brought to zero. There is now no existing female, except one mentally weak and childless, who has had uninterrupted female ancestors of the line back to the second generation.

#### HOMEOCHRONICITY.

Habershorn (Transac. Oph. Soc. Unit. King., 1888) gives a complete review of the literature of hereditary optic atrophy up to the time he wrote. In the great majority of the cases he reviews, the ages at which the onset of the disease occurred fall between 15 and 19. In both sexes the cases more or less roughly group themselves about the period of puberty, and that approximating 40. The cases I report decidedly neutralize this law, if such it may be termed, and throw the subject back into the mystery into which it seemed emerging. In the first three or four generations there was some approximation toward grouping about the age of 40, but in the last two generations the onset of the disease more clearly and decidedly clusters about the ages of full adult vigor, i. e., from 23 to 34.

In discussing the paper of Dr. Gould, Dr. Burnett, of Washington, D. C., said he had seen one instance in which the female was affected. The patient first examined was a boy of eight years, who had been nearly blind ( $V. \frac{3}{60}$ ) since early childhood. His mother, who was present, was examined and a similar condition of the optic nerve was found. The family history, so far as it could be ascertained, extended three generations back, but had always been transmitted through the females.

#### GLAUCOMA POR TRAUMATISMO OPERATORIO.

Por el Dr. E. LOPEZ, Habana, Cuba.

La discisión de la catarata secundaria se practica hoy día con frecuencia, y algunos cirujanos, con objeto de obtener el maximum de agudeza visual, desgarran sistemáticamente la cápsula por tenue que sea la opacidad.

Esta práctica obedece á la sencillez de la operación. Basta, en efecto, introducir una aguja apropiada ó un instrumento cualquiera puntiagudo á través de la córnea y desgarrar la opacidad, seccionándola en cruz, en T, en ángulo, ó del modo que el operador crea más á propósito para alejarla del centro de la pupila.

Como no siempre se logra obtener este resultado, hay que repetir la operación dos ó más veces, ó bien recurrir al procedimiento de deslaceración mediante dos agujas que después de encajadas en la opacidad, una sirve de apoyo, mientras que la otra la desvia obrando como una palanca, y vice versa.

Como se ve, nada es más fácil que practicar esta operación, cuya herida de la córnea puede estar cicatrizada al siguiente día, y el enfermo haber mejorado su vista.

Pero no siempre se tiene tan buena fortuna, y en prueba de ello me propongo demostrar que la discisión de la catarata secundaria va casi siempre seguida de glaucoma. Solo excepcionalmente deja de ser apreciable esta complicación.

Todas las veces que he desgarrado la catarata secundaria, ya sea con una ó dos agujas, un enchillette de Graefe, de Knapp, ó cualquiera otra forma que el instrumento tenga, que la desgarradura se haya hecho con las formas más variadas,

siempre se ha producido una reacción glaucomatosa más ó menos intensa. En el adjunto cuadro presento un resumen de 26 discisiones, que contiene el modo de operar, las complicaciones sufridas, y los resultados obtenidos.

El enfermo de la observación 24 toleró una segunda discisión con dos agujas, sin la menor reacción, puesto que el día después de la operación, apenas hubo una ligera inyección conjuntival. En la primera discisión, que se le hizo también por el mismo procedimiento, tampoco hubo dolor ni reacción marcada. En las observaciones 2 y 4 acusaron los enfermos un poco de dolor, y hubo inyección conjuntival periquerática, trastornos que se disiparon rápidamente.

En la mayor parte de los casos se declaró de las 4 á 10 horas después de la operación un ataque de glaucoma de mediana intensidad, con  $T > n$ . (aunque este síntoma no lo busqué en algunos casos cuando aún no pensaba en esta complicación), viva inyección de la conjuntiva al rededor de la córnea ó en toda su extensión, dolor más ó menos agudo, limitado al ojo ó extendiéndose á toda la rama oftálmica, dilatación pupilar, lágrimas, enturbiamiento de los líquidos intraoculares, disminución de la vista, y dificultad para mover el ojo.

Pero estos fenómenos, aunque alarmantes al principio, se disipan en el transcurso de algunos días.

En otros casos el glaucoma ha sido agudo, y tan característico que me ha decidido á ser sobrio y muy prudente en la práctica de esta operación. Referiré á grandes rasgos la observación 16, en que un glaucoma fulminante produjo rápidamente la atrofia de la pupila en medio de agudísimos dolores.

A un individuo blanco, de 57 años, artrítico, muy grueso y de cuello corto, le extraje la catarata de un ojo sin accidentes, y curó pronto dejando una secundaria bastante tenue. A los 32 días la operé con un cuchillete de Knapp, desgarrándola en dos direcciones y obteniendo inmediatamente una hermosa pupila negra, á traves de la cual vió claramente el enfermo. Esta operación se hizo con todo rigor antiséptico, y se usaron instrumentos nuevos. Después de terminada se aplicó un vendaje protector.

A las 24 horas de la operación se declaró dolor fuerte en el ojo que se irradiaba á toda la rama oftálmica, con sensación de tensión, con edema de los párpados y de la conjuntiva, con oftalmoplegia, exoftalmos, pupila dilatada, abolición de la vista y gran dureza del ojo. A las 40 horas tuvo escalofríos y vómitos repetidos y agravación de los síntomas antes indicados. El dolor se mostraba por punzadas intermitentes intensísimas.

El quinto día el quemosis conjuntival era aún mayor, y el enfermo en el colmo de la desesperación rehusó más obstinadamente que al principio la iridectomia que le propuse como único remedio que podía curarle con éxito.

Al cabo de una semana remiten todos los síntomas, pero persisten  $T > n$ , anestesia de la córnea, disminución de la vista y enturbiamiento del humor vítreo.

Desde esta época el glaucoma ha tenido accesos con intervalos variables. Al fin la cesación de los fenómenos agudos se ha debido á la distensión de la cicatriz de la primera operación, que á los 150 días parecía no existir en ella más que una ectasia formada por el iris retenido por algunas fibras córneo-esclerales. La pupila estaba en esa fecha muy dilatada, los humores intraoculares algo turbios y  $T > n$ , aunque menos duro que en el principio. La opacidad había quedado definitivamente rechazada al tercio inferior de la pupila. A traves de esta se veía la pupila atrofiada y totalmente excavada. El campo visual estaba muy reducido en todas direcciones (aunque con la particularidad de hallarse casi abolido del lado externo), y la vista había quedado reducida á la percepción de la luz.

Es indudable que este ha sido un caso típico de glaucoma agudo y que no tuvo otra causa más que el traumatismo operatorio.

Entre los ojos de tendencia glaucomatosa y otros refractarios á esta complicación hay una gradación que depende de la intensidad de la reacción uveal, y de la anchura de las vías excretorias.

Pero, ¿cómo puede la discisión producir el glaucoma cuando en tantos otros traumatismos operatorios no se le vé aparecer? Veamos primero lo que es el glaucoma. Lo considero como una consecuencia de la hipersecreción de la glándula uveal, si afecta la marcha aguda; y en la crónica lo creo debido á la deficiencia de las vías excretorias, haya ó no aumento en la producción de los líquidos intraoculares.

Partiendo de este principio me explico la génesis del glaucoma después de la discisión del modo siguiente: Al desgarrar la cápsula con cualquier instrumento que sea y con cualquiera forma que se dé al corte, se determinarán tracciones sobre la opacidad. Estas se transmiten al ligamento suspensorio del cristalino, que por sí y mediante numerosas fibrillas zonulares adhiere á la glándula uveal.

Sufre, pues, esta glándula en el acto de la discisión una fuerte irritación que se traduce por hipersecreción brusca de humor acuoso, y desde ese momento se habrá originado un ataque de glaucoma agudo, con todo el cuadro de síntomas que desarrolla el aumento de la tensión intraocular. Esto, en efecto, es lo que pasa casi siempre que se practica la operación.

Si las vías excretorias son amplias no llegará á constituirse el estado glaucomatoso; si son normales aparecerá el ataque, pero al cabo de algunos días se restablecerá el equilibrio de la tensión, y el enfermo habrá dominado la crisis. Pero en individuos predispuestos al glaucoma, como en los artríticos, ateromatosos y otros en quienes no sabemos sospecharlo, pero que consideramos que tienen todos de común la insuficiencia de las vías de excreción, el ataque puede llegar á ser brutal, y la vista quedará perdida ó gravemente comprometida.

¿Puede evitarse la aparición del glaucoma en las operaciones de secundaria? Se logra ciertamente suprimiendo las tracciones de la glándula uveal.

Desde luego creo más conveniente desgarrar la opacidad con dos agujas, de las cuales una sirve de apoyo mientras la otra desgarrar. De este modo se evitan al menos tracciones violentas. Sin embargo, en el cuadro que incluimos figuran casos de glaucoma siguiendo este procedimiento, de modo que no es grande la superioridad que ofrece sobre el empleo de una sola aguja.

Respecto al instrumento que ha de usarse me parece preferible un cuchillete puntiagudo á las agujas, aunque estoy seguro que ni con ellos se evita el traumatismo del epitelio de los procesos ciliares.

Soy parco en el uso de la discisión, sobre todo en los casos de secundarias espesas que necesitan fuertes tracciones para ser desgarradas.

La capsulotomía ó la irido-capsulotomía, en cambio, no ejerce la menor acción sobre los procesos ciliares. Así no debe extrañarse que á pesar de ser con ella mayor el traumatismo nunca dé lugar á un verdadero ataque de glaucoma.

Esta operación, aunque en extremo delicada por la destreza que necesita la introducción y corte de la pinza-tijera, tiene en cambio la gran ventaja de formar anchas pupilas y no tener complicaciones serias cuando se han empleado instrumentos asépticos.

Gracias á esta operación no tengo el disgusto de presenciar ataques de glaucoma. Cierto es que por lo común provoca una reacción moderada que se reconoce por la tumefacción del iris y por enturbiamiento del humor vítreo, y á veces inyección de los vasos subconjuntivales, pero con poco ó ningún dolor. La herida de la córnea cicatriza rápidamente, y el humor vítreo recobra su transparencia al cabo de algunos días.

Terminaremos proponiendo que se emplee contra las secundarias muy tenues la discisión con una ó dos agujas, prefiriendo esta última. Contra las secundarias espesas debe emplearse siempre la capsulotomía.

## THE ETIOLOGY AND EARLY MANAGEMENT OF GLAUCOMA.

By G. E. DEAN, M. D., of Scranton, Pa.

Although much attention has been given by authors to the subject of glaucoma, a great deal of the mysticism of the past has clung to it, causing most observers to class it with the inscrutable, while the few ventured to explain it by fine-spun theories. Believing that the theories of the causation of this important disease of the eye, which I learned from the text-books of a dozen or more years ago and which I heard taught in Vienna in 1887, must, from their very nature, be nothing better than fragmentary, I have been making some observations independent of theory, either dignified by age or newly preconceived. If the conclusions arrived at should, as I venture to hope, throw some light upon the etiology of the disease, give definite aim to the labors of the pathologist, and lead up to a more rational plan of prophylaxis or treatment than has prevailed in the past, I shall feel more than repaid for the effort expended in the researches.

My first observation was that the theory given in the excellent treatise of Soelberg Wells—mostly quoted from Graefe and which we may call the anterior inflammation theory—however attenuated, would not apply to all cases and was, therefore, untenable as a general theory. My next observation was that the theory taught us in the clinic of the celebrated Prof. Stellwag, by his first assistant, and which we shall call the choroiditis theory, while approaching a little nearer the bottom facts, did not at all cover the ground. It is evident that while degenerative choroiditis might be present in a good many cases, it was as likely to be a part of the pathological process as to maintain the higher relationship of cause to effect. Then I observed, year after year, that, with few exceptions, the cases of decided glaucoma, of threatened glaucoma, and of glaucomatous cupping without active symptoms, were in persons affected with astigmatism (frequently conjoined with hypermetropia); and it seemed to matter little how small the degree, 0.25 of a diopter being a not infrequent showing. Later I began to observe that the exceptional cases were myopes in whom a more or less similar condition of back pressure existed; or what is relatively the same, posterior weakness of the eyeball.

My next investigations led me into a study of the so-called "physiological cupping," and I found it such an elusive subject that I at last concluded that it was to a very considerable extent a delusive one. Perhaps the fairest explanation of it in all respects that can be given in brief, is to compare the whole subject with the inguinal canal in its healthy state, and its possibility of acquiring inguinal hernia. The conditions are analogous in the main, except as to size and the possible difference in time required to produce a similar effect from a similar cause. In both instances we have a point of weakness about certain vessels and subjected to more or less pressure from within. In each we may have this weakness exaggerated, it may be anywhere from a slight to an extensive degree, by a funnel-shaped depression or cupping outward which may be either congenital or produced. It is easy to understand that a tolerably constant undue pressure may gradually increase the depth of this cup or broaden it, and thereby gradually increase the element of weakness; or it may yield suddenly at the base and admit of a hernia *de facto*.

In the case of the optic disk, we have in perfect health, as it appears, an exceedingly slight depression about the vena centralis retinae, and also some less rigid tissue there, apparently intended by nature to afford greater safety to the vein. Now in the highest state of nature this slight depression has an area of elevation around it which acts as an excellent bulwark of protection; but let it be subjected to a continued excess of pressure, slight though the accretion may be, as in the eye strain of defective refraction, and we may observe that the interfibrillar substance of the nerve is absorbed, leaving a broad, shallow cup (the atrophic cup of Fuchs), or, apparently independent of that, we may notice in other cases quite deep retrocession at the temporal side of the central vein without any very noticeable lowering of the general surface of the optic disk. In the former cases (atrophic) there is apt to be also atrophic change at the periphery of the disk, while in the latter cases this factor is at least not so noticeable. I am disposed to regard both these conditions as intermediate stages between a healthy condition of the nerve on the one hand and glaucoma on the other, more especially as I have seen inflammatory glaucoma in an eye with one of the deep narrow cups and a decided tendency toward glaucoma simplex in another, and because it appears that atrophy of this kind favors the developing of glaucomatous cupping. The optic nerve is placed very much like the cork in a wine bottle, i. e., as if forced in, so that outward and inward it is larger than in the middle; hence an atrophy which reduces its diameter tends to make it push out more readily, thus displacing the lamina cribrosa backward and admitting of the well-marked glaucomatous cupping.

Having given a brief résumé of the course of utterly unbiased reasoning which led up to the conclusion, though without introducing the cases, which would be interesting enough if time permitted, we shall unhesitatingly announce the prime underlying cause of the disease.

The keynote of glaucoma is eye strain and that usually from some defect of refraction. There is no need to make a great mystery out of glaucoma any longer. If it were possible to correct all the errors of refraction in a given community, correct them early, and keep them continually corrected by suitable and absolutely accurate glasses, then, in that community, glaucoma, apart from a few secondary and traumatic cases, would disappear. We speak advisedly in saying a few, for it is highly probable that these cases have largely been predisposed to by eye strain. We apprehend that the elucidation of this subject has been delayed somewhat through reverence for the opinions of the immortal Graefe. It is indeed a high tribute to his genius that his doctrine on the subject should have been accepted as the law governing research almost up to the present time. Graefe did wonderfully well, as well as it was possible to do in his day, but the age is progressive and the greatly improved refraction work, at least of some of the more careful men in this country, makes it possible to take a deeper and more comprehensive view into the etiology of this and certain other diseased conditions of the eye. Our object should not be to combat the theory of this or that individual, but to lay a foundation under them. Some of them at least, and perhaps most of them, contain good material and make such a presentable showing that they deserve to have something better than mist to stand upon. While we have already been laying considerable stress upon back pressure, and while we believe that in the average case the posterior portion of the eye earlier receives the impression which tends in the direction of glaucoma, we must never lose sight of the general truth that eye strain, the cause, is bipolar in its action; hence we must comprehend the effects produced both posteriorly and anteriorly and must not be surprised nor disconcerted by the variations in type met with in studying the disease. It is but natural that when a force acts in more directions than one, the manifestations produced may vary in character. Of course, in speaking of posterior strain, we are referring to that which takes place in and about the optic disk; and of anterior strain, referring to that which occurs in and about the ciliary region, including a tolerably large and important area. We further must not ignore the fact that there is lateral pressure as well, and that the venæ vorticosæ are important elements in the circulation of the eye. And perhaps there has not enough stress been laid upon the ease with which the retrochoroidal lymph space may become affected.

Concerning the effects of anterior pressure, it is not necessary to say much here, for the reason that it is so well described in the text-books. Most of them doubtless attribute undue importance to disturbances in Schlemm's canal, as etiological factors; they are important enough to be sure, but it should be borne in mind that there are other and larger lymph channels in the eye. A close observer may notice that in a great many cases interference with filtration in that direction is the final act of a rather long ocular tragedy.

A strong argument that the early pressure effects are not so much forward as backward, is that so little scleral congestion is observable in the inflammatory cases compared to what is seen in iritis, cyclitis, etc. No wonder the scientist looked in vain for the cause during the attack, when the cause has been acting more or less quietly for years until the attack obscured it, and rendered critical study impossible. It should be remembered that in thousands of non-glaucomatous cases the same cause (eye strain) is acting, but finds enough resistance to prevent a glaucomatous effect from being produced. The optic nerve often withstands the strain so long and with so little local deleterious effect that we can but marvel at its power of endurance; and even when some retrocession has occurred, oftentimes no startling symptoms arise until the lamina cribrosa has been forced back to such an extent that the pressure in part is applied in a lateral direction almost directly upon the nerve sheath, upon the lymph channel surrounding it, and only less directly upon the posterior ciliary circulation. Likewise forward pressure in the ciliary region (i. e. practically in the opposite pole) is endured fairly well until it causes an impingement upon the

absorbent angle of the anterior chamber. But it will be observed that these are only climaxes in a process long since begun. It is highly probable also that in a considerable percentage of cases, strain at one pole is endured until too much strain is applied at the opposite pole; then the patient, suffering eye succumbs to overwhelming forces. In another of the diseases to which flesh is heir, viz, peritonitis, we have what may answer as an example in some respects of what is meant. So long as a peritonitis (nonpurulent) remains localized, it may seem comparatively insignificant, but let it assume a general form and all will admit its gravity.

Space will not here admit of going exhaustively into the subject of eye strain, but a few points may be briefly touched upon. We shall premise by saying that the term has too often been restricted in many minds, almost entirely to the apparatus of accommodation, rather ignoring the important part played by the recti muscles. It is true that, apart from myopic eyes, a large percentage of the strain comes from near work, and hence glaucoma as a fully developed disease is largely confined to persons of more or less mature years, when the eyes find some added resistance to the efforts of accommodation. It accounts also for its relatively greater frequency in hypermetropes. We should not be surprised to find, if sufficient statistics were available, that the average onset was a little earlier in hypermetropes than in some other classes of cases, just as we notice in them the relatively earlier necessity of wearing glasses for reading. A very possible reason why myopic eyes are less frequently glaucomatous arises from the fact that many of them do not find much difficulty of accommodation. Another factor is found in the general weakness of the posterior wall of the globe, making the excess of pressure relatively less felt at the disk than in hypermetropic cases.

Understanding that astigmatism is one of the greatest causes of eye strain, we must consider that the ideal eye for the production of glaucoma would be one with hypermetropic astigmatism. It is known to be rather frequent in such eyes, and doubtless a great many glaucomatous eyes classed simply as hypermetropic really had a slight astigmatism which was undiscovered. Statistics show that very few emmetropic eyes have been affected with glaucoma, so few indeed that it is exceedingly probable that they were cases of mistaken diagnosis.

If space permitted, we would refer to general conditions of the circulation and the system at large; to tonic spasm of the ciliary muscle, intra-nasal pressure, etc., as possible etiological factors. For the reason indicated it is impossible here to give a detailed explanation of our views regarding the mechanism of eye strain.

If the pathologist will take his cue from the clinical facts that eye strain is the general underlying cause of glaucoma, and further, that the earlier effects, so far as tending towards glaucoma are concerned, may be exerted backward quite as frequently as forward—perhaps far more frequently—he will soon find that the study of this disease does not lead him into such a mystical field as it has been pronounced by most of our authors. If then he will turn his attention to the admirable schematic cut in Fuch's Textbook of Ophthalmology, page 251, showing the lymph passages of the eye, and, observing how extensive they are, decide to make a general study of them in connection with glaucoma, he may find a rich field for investigation and produce some decidedly definite results.

#### EARLY MANAGEMENT OF GLAUCOMA.

It has been thought best to refer to the plan of treatment provisionally adopted as the "early management of glaucoma," for the reason that it applies primarily to those cases of glaucoma and threatened glaucoma which early come under the observation of the oculist; and it would be manifestly unfair to apply it only to a few neglected and desperate cases found in metropolitan hospital practice, and then reject it as unworthy. Of course, in this disease even more than most others, prevention is better than cure. The chief measure of prophylaxis is the early use of accurate glasses; but medication is also useful in that direction. The medica-

tion must, however, be followed up by glasses and no pains must be spared to make them exact. Of therapeutic measures perhaps the best we have as yet found are acetanilid internally, pilocarpine solution instilled into the eye, and the hot solution of boracic acid applied externally. The acetanilid has mostly been given in 8-grain doses, three or more times a day to the average adult, and 4-grain doses to specially susceptible females. Its action should be watched so that it shall not cause too great depression; and if the temperature is found subnormal, the dose should be lessened. My reasons for preferring pilocarpine to eserine are twofold; first, that while it may not be so strong a myotic, it seems to have a better effect in reducing ciliary congestion; secondly, it allays pain instead of causing it, as eserine does. We know of no reason why the strength of the solution should not be increased in critical cases; but 4 grains to the ounce is as strong as we have used. Whether the salicyllate of sodium does good of itself, we can not say positively, but at any rate it preserves the solution, and we have sometimes fancied that the pilocarpine solution was more efficacious when combined with it. So we invariably use it at the rate of 10 grains to the fluid ounce. Very possibly it may be found that hypodermic injections of pilocarpine (one-sixth grain) may be of service, but I have thus far never used them in this connection, preferring to rely upon acetanilid as internal treatment. Unless the patient was kept in a recumbent position and the circulation and temperature noted it would not be safe to make use of both these depressing agents at once. Perhaps we may find cases wherein this, as in so many other diseases, the recumbent position is highly advisable; but oftentimes the pain is of such a character as to make the patient restless instead of causing him to seek repose. For the hot external applications the patient was allowed to make an extemporaneous solution of boracic acid, but the mode of applying was as specific as possible. The applications were made with soft cloth dipped frequently (once a minute), kept at about the highest comfortable temperature, and continued twenty minutes each time. The frequency of repeating them varied with the case, from once a day to every three hours, or oftener. We had hoped to obtain favorable results from the use of gelsemium, but, at least in the dose employed, it did not yield as favorable results as acetanilid.

The early employment of temporary glasses is a measure not to be neglected in certain cases, for in these irritable eyes a sensible man will not attempt a great amount of subjective testing for glasses; and we doubt if many cases retain the same refraction when the acute and the subacute symptoms have passed that existed during those stages.

Regarding iridectomy in this disease, we are confident that it is an operation which will fall more and more into disuse. It was an empirical operation at best, and though it served a very useful purpose in its day it has comparatively little place in attending to the better-cared-for eyes of the present. While it may still remain a desirable procedure for certain urgent and neglected cases, it does not always produce satisfactory results, and should by no means be lightly adopted as routine practice.

---

#### DISCUSSION.

Dr. MCFARLANE. I am glad to know that some one has had such universal good fortune following operations for glaucoma. It has not been my fortune, nor the fortune of those with whom I have been most familiar, except in acute or subacute forms of the disease. I would refer to the report of a group of cases by Dr. C. S. Bull, of New York, in which the results were far from satisfactory. I think medication valuable as well as iridectomy, which can not be discarded.

Dr. TIFFANY. In my first years of practice in Kansas City I had frequent cases of acute glaucoma; of later years they have been less frequent. I attribute this to the fact that the cause has been largely removed by the universal correction of low

forms of ametropia, as of hyperopia, of astigmatism, and of hyperopic astigmatism in particular.

Dr. REDMOND. I speak more through observation here and abroad, as these cases are not by any means common, yet in my experience I have found that surgical interference is almost always necessary. Cases in which I have seen iridectomy fail have been generally attributed to corneal vision instead of scleral.

Dr. ALT. Dr. Dean claims that eye strain is the cause of glaucoma. If it was the cause a great many more people would have glaucoma. There must be something else behind the eye strain, which even this paper on the etiology of glaucoma does not clear up, and for which no theory has yet fully accounted.

Dr. BAKER. The last case but one which I operated upon for glaucoma was in an old lady 74 years of age. If glaucoma is due to eye strain, as stated by the essayist, how would you explain it in such a case as this?

Dr. SAVAGE. Yes. In the old there is no ciliary strain; but strain of the recti or obliques can exist at 120, or any age. Such strain begins in infancy and ends only with death, unless relieved by treatment.

Dr. S. S. HOSER. I am loath to believe that these cases come to us sufficiently early to make out with exactness these low grades of refraction. Certainly those who come to me are. And as to therapeutic management, I have not seen much success therefrom. On the contrary, rather let us operate early, while it is yet possible to do an iridectomy neatly, and not wait until the iris is so degenerated that an equally clean operation can not be done.

Dr. TYNER. I have my doubts as to the existence of chronic glaucoma and to eye strain. They rarely ever come to us in time for correction. Most of my cases have been in persons who were poor and did not use their accommodation. That a real and timely-made iridectomy is mostly successful I am sure.

Dr. J. J. CHISOLM. While an iridectomy is the only reliable treatment for glaucoma, especially the acute forms, I have sometimes derived such excellent results from eserine as to do away in some instances with the need of the operation. Only to-day I saw a case in a gentleman whom I had first seen in August, fifteen days since. He was 62 years of age and had been suffering intensely for ten days with inflammatory glaucoma in the left eye. The eye was much injected, pupil enlarged, anterior chamber obliterated, tension marked, and sight reduced to counting fingers. The cornea was too steamy to give the fundus definition with the ophthalmoscope. He had walked the floor all night from severe pain. I determined to prepare the eye for operation by trying to establish an anterior chamber by use of a 1-grain solution of eserine instilled upon the cornea six times a day, and advised the use of the Japanese hot box for dry heat. The temperature of about 115° was kept up for two hours at a time and was ordered three times a day. The heat relieved the pain and by the next day I found the pupil contracting. The eye steadily improved until at the end of a week all congestion had disappeared, and with it all pain. Sight had returned as the congestion subsided, and to-day when I saw him there was no need of an operation at present. Sight is normal, congestion all gone, and, with the exception of a much-contracted pupil, the eye looks quite as well as the other, which was not affected. How soon there may be a repetition of the glaucomatous attacks in this individual case I am not able to say. I have other cases of two years' standing that I have relieved as promptly as in this instance and they remain cured. I am beginning to have so much confidence in the eserine and dry heat for the relief of acute glaucomatous attacks that I am quite ready to advise this treatment as a preparation for an iridectomy should the relief not come in a few days' use of the remedies. For convenience, cleanliness, and the very great advantage of keeping up the same temperature, I would call the attention of the section especially to the Japanese hot box, which is in universal use in Japan to relieve pain in all cases in which we apply moist heat. They can be found at all stores selling Japanese goods. The boxes, as we find them, not made for eye work, are about the size of the hand in length, breadth,

and thickness. A charcoal fire is used for heating. Under the slow combustion of the box it will burn for about two hours and will keep up a temperature of from 115° to 120°. I have had them in general use, both at my hospital and in private practice, for fully three years, and I know no substitute for them in any case of severe eye congestion, especially in glaucoma. Patients who have once used it fly to it for relief with confidence whenever the pain recurs.

In closing the discussion Dr. Dean said:

I am very glad that so much discussion has been elicited. And it was not to be expected that so learned a group of scientific gentlemen would accept all the ideas advanced unchallenged; it is not in the nature of things. My object was to start up trains of thought that might lead to useful results. My leading idea was to explain the underlying or predisposing cause of glaucoma; not to combat the operation of iridectomy as such. I believe in iridectomy in suitable cases, where the rapid reduction of tension is an urgent necessity. What I meant was that, by beginning early with suspicious cases, its application might be gradually circumscribed. I also ventured the prediction that it would be less often required in private practice as the people learned to take earlier and better care of their eyes, aided by the painstaking efforts of skilled oculists.

---

### CATARACT EXTRACTION WITH THE IRIS RETRACTOR.

By FRANCIS VALK, M. D.,

*Instructor, Diseases of the Eye, New York Post Graduate School and Hospital, etc.*

Since the early part of 1887, I have performed the operation for the removal of cataract by a method somewhat different from that usually adopted. This I have placed before the profession at the Post-Graduate School, at the State society, and also at the meeting of the New York Academy of Medicine, but, owing to unforeseen circumstances, there has been no opportunity for my colleagues of New York City to criticise or to discuss the merits or demerits of the retraction of the iris, and the removal of the lens at the same time. I have, therefore, asked the honor and the privilege of bringing this matter before the congress, that it may meet with a full and a fair discussion. I shall always highly appreciate the opinions and suggestions of those who have entered this special branch of surgery, before I attempted to step on the first round of the ladder of fame, as well as the remarks of those who are working side by side with me in trying to advance this noble art, even though our efforts may not meet with the approval of all, still we hope these are but steps forward, if I may call them such, that they may some day fall into the hands of men who may so improve them as to produce far better results.

I do not propose to discuss the merits of the different methods for the removal of the sclerosed lens, which intercepts the rays of light, nor the special features of an operation with or without an iridectomy, as the advantages of a round and normal pupil are well known and obvious. Nor yet do I believe there will ever be a day when the conscientious surgeon will adhere strictly to only one method of operation, but will always adopt what he thinks best for the ultimate good of his patients. Therefore it is my intention in this paper to suggest some thoughts and methods that have occurred to me in the course of my limited number of operations and to explain the uses and advantages of the simple little instrument, "the iris retractor," that I have used whenever possible during the past four years.

As regards the time to operate. I think that this should be decided, when we find the cataractous lens sufficiently hardened to admit of its ready removal, without any reference to what the vision in the other eye may be. If our patients are willing to have an operation performed, even though the vision may be good in one eye, say  $\frac{2}{3}$ , then you are justified in taking the slight risk there may be of failure for the

benefit of the improved binocular field of vision. The blindness on one side renders our patients at a disadvantage, as some of my cases will show; at the same time we make a useless eye ready for practical vision, when its fellow lens become opaque.

*Preparation for the operation.*—We may do nothing as regards the ultimate success, except so far as we may have the minds of our patients completely at rest. In the light of the present statistics, the chances of failure in a healthy eye, if a cataractous eye can be healthy, are very small, as you may see by the reports of cases lately published. So I do not in any way prepare my cases beforehand, and particularly avoid the use of atropine before the operation.

*Operation.*—At the time when I am ready for the operation, I instill a sufficient quantity of a solution of cocaine, 4 per cent., to render the cornea anæsthetic, but not to dilate the pupil. The patient is then placed on a steady table or bed with a good clear light on the eye, and the lids opened with the speculum. The eye is then washed with a solution of boracic acid while my instruments are all placed in boiling water and then on a clean towel and covered until wanted.

*Section.*—This I consider the most important part of the operation, as upon a good section, I believe, depends the ultimate success. This should be in the same plane, except at the finish, as I shall describe. I wish to avoid the conjunctival flap, and by the perfect coaptation of the wound in the cornea we may avoid slow healing, septic infection, and prolapse or incarceration of the iris. I make the section either upward or downward, according to the eye to be operated upon, as upward in the right eye, downward in the left eye, or, if the operator is ambidextrous, then both sections may be made upward, as I consider the upward section preferable. I prefer, in making my section, to cut always towards myself, for in so doing we produce a much smoother and clearer cut. I always make the puncture and counter puncture wholly within the corneal tissue, through its transparent margin, about 1 millimeter from its periphery and so that the cutting edge of the knife will just cover the pupillary edge of the iris on the side toward which I propose to make the section. If possible I rapidly make the section of the cornea with three distinct cuts; first, carrying the point of the knife, as soon as the counter puncture is made, upward and forward, cutting one side of the cornea; then the heel of the blade is drawn upward and backward, so cutting the opposite side; then turning the knife on its long axis, the section is completed with the third cut by pushing the knife steadily forward until released. I think De Wecker, of Paris, first suggested this method, and I prefer it to all others. As I complete the section in the above manner the knife comes out some distance from the scleral junction, leaving room for the iris to be tucked in, when drawn back by the retractor. At this time we may have prolapse of the iris; if so, it must be returned with the spatula, if we wish to save the iris; but if not, then it may be drawn out and cut off, if we decide that an iridectomy is best. Another complication that may occur at this stage, particularly in very old people, is the rupture of the capsule or the zone of Zinn, with the presentation of the lens at the section; if so, it must be removed at once by pressure on the cornea. I am inclined to think that should there be any tendency to prolapse at this stage, it is better to perform an iridectomy at once, to prevent any future prolapse as the healing process proceeds. If no complications arise I then proceed to open the capsule by a peripheral incision, passing the cystitome inward to the pupillary space, then under the iris, and sweep it around beneath the edge, so as to cut the capsule in more than one-third of its periphery on the same side that the section has been made. My next step is the drawing back of the iris and the extraction of the lens.

At this point I wish to say a few words in reference to my method of the retraction of the iris with the little instrument called the "iris retractor," which I now present, claiming that I first adopted and practised this method. In the Archives of Ophthalmology, May, 1888, page 60, Dr. Herman Knapp states that, before and since I read my first paper on this subject, he had drawn back the iris toward its periphery when he found that membrane somewhat rigid, using the small wire

loop, but he does not state that he held the iris drawn back until the lens was removed, so I infer that he simply drew it back to relieve its rigidity, or to break up any adhesions that may have formed between the iris and the anterior capsule. Again, I find in an article by Dr. Barton Pitts, of St. Joseph, Mo., in the Medical Record of October, 1890, wherein he claims a method of operation by which he draws back the iris with the same wire loop which Dr. Knapp used, and held it there until the lens passed out by pressure on the cornea. In the same paper Dr. Pitts criticises my retractor, when, according to his own admissions, he has never seen my instrument, nor does he even know its construction, but has simply followed out my ideas of drawing back the iris and holding it tucked back until the lens is removed. He does not give me the credit of having first adopted that procedure, though his ideas may be original with himself.

I will quote Dr. Pitts's words:

By Dr. Valk a distensible shield with two knobs is proposed. The method of its manipulation is to insert through the corneal wound, cover the surface of the iris, and by the knobs holding in the pupil, retract the iris upward as far as necessary and slide the lens over the front surface of the shield. Dr. Valk reports good results with it. I have not tried it, nor am I familiar with its pattern except from description. I should think, however, it objectionable, on the score of occupying considerable space, already too limited. Its insertion, moreover, I think awkward, and in the event of sudden movement of the eye under operation its presence in the anterior chamber especially dangerous. \* \* \* To overcome the resistance of the iris and frequent rigidity of the pupil, I have for two years resorted to the same instrument recently mentioned by Dr. Knapp as used by him; that is, a fine wire loop attached to a delicate handle. This instrument, which can be easily and thoroughly sterilized, I insinuate through the corneal wound into the pupillary space and retract the iris into the superior triangular space, and by a gentle pressure backward and upward of a strabismus hook applied against the lower edge of the cornea, I have little difficulty in the delivery of the lens and without material injury to the iris, and in no instance accompanied by loss of a single drop of vitreous, or followed by septic infection of the eye.

I have quoted his remarks thus fully, that you may note the different methods, and also if this little instrument is at all objectionable because it occupies too much space, or is especially dangerous in any sudden movements. I have never found it so; and in reality this retractor of mine does not take up any more room than the wire loop, nor is it "awkward" in any sense, as it can be easily removed from the eye by simply tipping up the ends of the blades, thus instantly releasing the iris. It seems to me that the construction of this little instrument is extremely simple, having only two small smooth knobs on the ends of a pair of forceps, with crossed action, and the size of the ordinary iris forceps. These little knobs, standing at right angles to the axis of the ends of the blades, and pointing downward, simply hold the iris tucked back in the superior triangular space until the lens passes into the corneal wound, when the iris is at once and easily released. When we consider the ease with which the lens passes out and the slight pressure required on the cornea, so much less than in the simple extraction universally adopted at the present day, I feel justified in claiming some merit and originality for this little retractor.

The eye being now ready for the extraction of the lens, it is grasped by the fixation forceps directly opposite the section, and held steady by a careful assistant. I now take the retractor in the left hand and with the blades closed and the set-screw so arranged that the blades will open to about the diameter of the pupil, I insinuate the ends through the section to the pupillary space. The blades are now opened by pressure and the iris drawn back and tucked beneath the edge of the lower corneal section. Holding it steady in that position, a slight pressure is made on the opposite side of the cornea, by a spoon or hook, causing the lens to rise up and easily pass out over the ends of the blades. As it does so, and as soon as the lens presents itself at the section, the retractor is pushed slightly inward, at once releasing the iris. The retractor is then generally removed, with the lens lying in the concavity of the blades. As the lens clears away we find the iris back in its position, not injured in

any way, nor has it been exposed to the air, as may occur in simple extraction. In case there should be any cortex remaining, which I do not think will be absorbed or will interfere with the vision, I have reintroduced the retractor, and, drawing back the iris again, these masses are easily pressed out with the spoon.

This completes the operation, and the section being in perfect opposition, the speculum is removed, the eye gently closed, and the bandage applied.

*After treatment.*—There seems to be as much diversity of opinion as regards the method of after treatment of an operation at the present day as there is in the methods of operation, even so far as not to use any bandage or dressings of any kind. I note that Prof. Knapp does not close the eye until about half an hour after the operation, in order to see if there is any tendency of prolapse. He only applies the cotton and isinglass slips, while Chisholm, of Baltimore, does not even apply any cotton; but as I have watched the healing process of my cases and noted the different conditions under which my patients have, from necessity, been placed, I am inclined to think that it is best to take a happy medium with a decided modification of the old strict method in use some years ago. Our first consideration must be the ultimate success of the operation and next the daily comfort of our patients as the healing process proceeds. Bearing these two points in mind, it seems to me that there will be fewer movements of the eye, and consequently less pressure on the sclera by the straight muscles, if we close both eyes with a neat-fitting flannel bandage with pads of absorbent cotton over the eyes. The slight restraint of a day or two in bed will not cause any distress, while the rest and quiet will assist in the rapid healing of the large corneal wound. I do not doubt but that those who use modified dressings have as good success as can be wished for, though the above ideas seem to me the best that we may employ to complete the healing of our patients, according to the old motto *Tuto, cito et jucunde*. I remove the bandage from the eye not operated upon at the end of forty-eight hours, or on the second day, as I do not wish, nor do I see any need, to keep these old people in the dark any longer than is absolutely necessary.

In my last four cases I have tried to carry out my ideas of non-interference still further, as I sometimes think that atropine may irritate an eye which has been operated upon for cataract, and lately I have not used this drug unless necessary; that is, when there were indications of commencing iritis; but I have changed the bandage every twenty-four hours, washing the lids carefully and gently with warm water, applying a little vaseline to the edges of the lids, and then replacing the bandage.

Now I wish to make another suggestion in reference to that desire which we perhaps all have, to look at the eye and to see the result of our work. Is it not better to leave the eye alone until all possible danger of complications has passed? Some of us have noted an opening of the wound or prolapse of the iris as late as the sixth day after the operation. Therefore I have decided to simply change the dressings every day for about ten days, unless there are some indications otherwise, and then open the eye in a darkened room, gradually accustoming it to light by the use of smoked glasses.

Prof. P. D. Keyser, of Philadelphia, and Dr. W. Buss, of Bradford, Pa., have used my retractor in several cases, and have reported to me good results, each being pleased with the easy exit of the lens and the rapid healing of the wound in the cornea.

In conclusion, I do not think that the surgeon who considers the best interests of his patients and the various conditions that may arise during an operation for the removal of cataract will persistently adhere to any one method of operation. In my own cases I have been compelled to lay aside the retractor in four cases out of thirty-three. So the surgeon must adopt that method which to him at the time seems best for the success either with or without an iridectomy, but we can adopt some method and endeavor to carry it out, unless we find it will endanger the final results.

Some of my cases have required a subsequent discussion, but as each case of that kind requires special study and method in itself, I will not make any particular reference to it, except so far as I consider Dr. Knapp's remarks as to the operation, delivered at Detroit, as the best and giving the final results required.

In the following table I give the histories of 29 cases in which the retractor was used:

| No. | Sex. | Age. | Name.         | Eye. | Iris pro-<br>lapsed. | Conditions, com-<br>plications.      | Results.                                                                                               | Remarks.                                                                                                       |

| 29  | F.   | 55   | C. D.....     | R.   | No.                  | .....do.....                         | $\frac{20}{30} \text{ u} + \frac{1}{4} \text{ c} + \frac{1}{10} 18^\circ$                              |                                                                                                                |

Final results:  $\frac{20}{30}$ , 1;  $\frac{20}{40}$ , 2;  $\frac{20}{30}$ , 8;  $\frac{20}{20}$ , 5;  $\frac{20}{40}$ , 3;  $\frac{20}{100}$ , 4; shadows, 4; no result, 1; no test, 1; total, 29.

In all these cases I have used the retractor, though some of them have presented indications almost against its use; but the final results have seemed equal to that of any other method, while in four cases not reported I could not use the retractor and the final results were not as satisfactory, and in one case where I performed an iridectomy the end was total loss. This method is perfectly safe and the retractor can, if necessary, be quickly and easily removed from the eye, while the objection once raised, that it is another instrument introduced into the eye, is not tenable, as this instrument is so easily sterilized; and besides I think there is less manipulation of the iris than in simple extraction, particularly if the iris is prolapsed at the exit of the lens. I will close by stating that by this method I do not meet with any more accidents or risks, as loss of vitreous, etc., than usually occur by other methods. I believe that with the careful use the retractor, as I now present it, and as I have used it for the past four years, material service will be rendered to the ophthalmic surgeon in the removal of the cataractous lens.

This instrument may be procured from E. B. Meysowitz, of New York City.

## HÆMORRHAGIC GLAUCOMA; ITS NATURE, PROGNOSIS, AND TREATMENT,

By S. D. RISLEY, M. D.,

*Lecturer on Ophthalmology in the University of Pennsylvania; one of the Attending Surgeons at the Wills Eye Hospital, Philadelphia; Professor of Ophthalmology in the Philadelphia Polyclinic and College for Graduates in Medicine, Philadelphia.*

*Case 1. Hæmorrhagic retinitis; secondary glaucoma; iridectomy; paracentesis and second iridectomy; enucleation.*—April 22, 1884, Mr. E. W. G., æt, 53, a merchant from the interior of Pennsylvania, a tall, spare man with iron-gray hair and swarthy, opaque skin, consulted me regarding the rapid and serious failure of vision in his right eye. His general health was much impaired, which he ascribed to financial troubles followed by tedious litigation, which had disturbed him very much and left him, according to his own statement, a nervous wreck. This had occurred eight years before, since which he had suffered more or less with impaired digestion and extreme nervousness, with spells of great mental depression. His hands and head were in a state of constant agitation, as in progressive palsy. The reflexes were normal and he was free from pain. The urine was acid, but exhibited no trace of albumin or sugar, but at intervals deposited copious quantities of red sand. The radial arteries rolled rigidly under the finger, but there was no gross lesion of the heart, although he was readily winded on the slightest exertion. He had not suffered from what he recognized as gout or rheumatism. O. D. V. = Counting fingers at 0.50 m. Tension normal, no contraction of field. O. S. + 3 D. V. = 6/vi. Tension and field were normal.

The ophthalmoscope revealed in O. D. a plainly vascular iris and small pupil; H.=3. D., small, dark-red optic nerve with indistinct margins, and scattered throughout the eye ground were innumerable small hæmorrhages, some of which were flume-shaped with fimbriated extremities, while many others were simply minute red points. The arteries were small and exhibited gray and ragged margins as far as they could be traced into the periphery of the eye ground. The light streak was for the most part absent. The veins were relatively large and full, their margins gray, and exhibited the light streak far more than the arteries. No aneurismal dilatations were noted.

O. S. H.=3. D. The general condition of the eye ground was much the same as in the right eye, but there were no hæmorrhages and the disparity in the size of the arteries and veins was less marked. The pupils in both eyes were small and dilated on by small medium under homatropine. The serious nature of his trouble was explained to him and an unfavorable prognosis given. His daily life was carefully regulated, the diet restricted, exercise in the open air enjoined, and he received potassium iodide in increasing doses. A saline water was to be taken in sufficient quantities to keep the bowels in a lax condition. In two days he returned much encouraged by the improvement in his general condition and his vision had risen to  $\frac{1}{24}$ . There were no new hæmorrhages and the eye ground was less deeply red. The treatment was continued and he received, in addition, a weak solution of eserine sulphate to be instilled in each eye night and morning. In one month he had gained 15 pounds in weight, but his vision had made no further improvement. The tension in the right eye was questionably increased, but the hæmorrhages had largely been absorbed. The field of vision remained normal. He was then taking 20 grains of the potassium iodide three times daily and this, together with the eserine, was continued. One month later, on May 25, the right eye became painful, which he attributed to a severe cold he had taken. The eye was not red, but subsequently became so, and the pain became so severe that he at once set out for the city. The eye was found a cinnabar red, the cornea steamy and insensitive, and the ball stony hard. The pupil was small and fixed, and the iris was plainly vascular. There was no change in the left eye, v=6/vi. A stronger solution of eserine was freely instilled and blood extracted from the temple. After the extraction of the blood, notwithstanding the free use of eserine, the pupillary diameter promptly increased to 4 mm. No view of the fundus was obtainable. The following day he reported great relief from the treatment, which lasted until after midnight, when the pain returned with great violence. Blood was once more taken from the temple and iridectomy advised. This was promptly done; the operation, notwithstanding the shallow chamber, was fortunately smooth, but the hæmorrhage following the excision of the iris was profuse and persistent, so that in the end the eye was closed, with the anterior chamber filled with blood. The wound healed promptly and the blood clot slowly absorbed. The tension became normal once more and the pain was entirely relieved. In two weeks Mr.

G. returned to his home with the eye white, free from pain, but totally blind, notwithstanding which he was very thankful for the relief experienced and the once more rapid improvement in health which followed. On the tenth day after his return home he suffered a severe attack of cholera morbus, accompanied with violent emesis and purging, which greatly weakened him. In twenty-four hours after the attack the iridectomized eye became uncomfortable, the discomfort rapidly developing into severe, unendurable pain, which, on the fourth day, once more drove him to the city for relief. The eye once more presented the cinnabar injection, characteristic of the glaucomatous eye, was stony hard, and the anterior chamber occupied by a large blood clot. He was suffering greatly and was completely broken in health. Enucleation was pointed out as the only sure source of relief, but to this he strenuously objected. Eserine and local depletion gave no relief, and so paracentesis of the cornea was done, affording instant freedom, except from a dull periorbital pain, the relief continuing for several days and  $T. = + 1$ . In a week the symptoms were upon him again with a new clot in the anterior chamber. He still refused enucleation, and with full understanding of the uncertainty of relief, submitted to a second iridectomy, which was made below with a Graefe knife resulting in a broad coloboma well placed. To my own surprise this also healed kindly, afforded complete relief for six days, when he received a telegram announcing the death of a favorite grandchild, which greatly depressed him. The following day he had an attack of acute indigestion, which in turn was followed once more by increased redness of the eye and pain; the tension, which had been subnormal after the second iridectomy, became too high, but the ball not stony hard, as before. The symptoms steadily increased in violence for several days, but were relieved by the digestive derangement ending in a profuse diarrhoea with many liquid stools. The relief was only transient, however, and after suffering several recurrences of pain, accompanied each time with fresh hæmorrhage into the anterior chamber, he gave up the fight and submitted to enucleation on August 9, rather less than four months after the first-noticed impairment of vision. Mr. G. has been seen from time to time since 1884, but at no time were hæmorrhages detected in the left eye, although he had frequent alarms by spells of imperfect vision. A letter dated July 17, 1893, says, "My left eye has been good until last March, then the sight became very dim; could not read, but is now much better; can read with ease and comfort."

*Case 2. Hæmorrhagic retinitis; secondary glaucoma; iridectomy; enucleation; followed in six years by similar attack in other eye; iridectomy; total blindness.*—On May 15, 1884, Mr. O., æt. 65, came to me bearing a note from his physician, Dr. Hinkle, stating that two months before he had had an attack of retinal apoplexy; that his urine on several occasions had contained traces of albumin, but lately this had disappeared. He had had several attacks of vertigo, but none within the past two weeks. His treatment had been antiphlogistic, with care as to his diet, rest, and iodide of potassium.

Mr. O. was actively engaged and much engrossed by the details of a large business, and lately had been much troubled over its uncertainties and by the sudden and unaccountable disappearance of a son. He was about 5 feet 6 inches in height, entirely bald, weighed about 250 pounds, had a florid face, and although an abstainer from alcoholic beverages, was extremely intemperate at the table, eating large quantities of richly prepared foods, not hesitating to wash his roast beef into his stomach with quantities of milk. His temper was extremely aggressive and his manner always that of command. His career had been one of many vicissitudes, having been driven as a Union man from one of the border States during the war, at the sacrifice of a large fortune, which at æt. 65 he was struggling with might and main to recover. In March, 1884, after spending an entire morning in his counting room reading and answering letters, noticed, on getting into the street, that his vision was defective, and the following evening the sight in the right eye had sunk to the ability to tell light from darkness. He consulted an oculist, who advised him of his apoplexy of the retina and gave him an unfavorable prognosis both as to vision and health. Under the wisely prescribed regimen and the potassium iodide prescribed by his physician, Dr. Hinkle, he had lost 14 pounds in weight.

St. Pro. O. D. No perception of light; ball stony hard; cornea steamy and insensitive; deep ciliary injection; shallow anterior chamber; pupil 4 mm. There was profuse lachrymation, and the eye was kept closed as though from photophobia; violent pain in the eye and severe hemicrania. No view of fundus admissible.

O. S., white, free from pain, anterior chamber shallow, pupil small,  $T. + ?$ ,  $Hm. = 2.50$ ,  $D. V. = 6/ix$ . Optic nerve gray, and at its upper part a few small, reddish points, probably absorbing hæmorrhages. The pupil was too small to

permit of a satisfactory study of the macula lutea. There was concentric narrowing of the field to  $30^{\circ}$ . There was periodically a profuse deposition of uric acid and he was subject to fits of despondency and irritability. The radials were rigid, but no serious lesion of the circulation was discovered other than that existing in the retina. The serious nature of his trouble and the threatened onset of disease in the left eye were pointed out. Locally eserine, and leeches to the temples were directed. Free purgation and a rigid diet list, with exercise in the open air and entire absence from business and even moderate use of the left eye, were insisted upon. Two days later the pain was less and the steamy condition of the cornea had diminished. Iridectomy was then made upward, a broad coloboma well back being secured notwithstanding the great difficulties presented by the shallow anterior chamber. The aqueous was allowed to escape slowly, but profuse hæmorrhage followed the excision of the iris, and the eye was bandaged, with the anterior chamber filled with blood. The pain was at once relieved, but two days later the lids were puffy, the blood clot still present, and the wound open. The eye recovered slowly, with a filtration cicatrix. There was no return of pain, but there were frequently recurring hæmorrhages in the anterior chamber until August 8, two months after the iridectomy, when, after consultation with a colleague, he consented to enucleation. He was urged to continue his general regimen as directed, under the care of his physician, and disappeared from observation. In the left eye vision remained as at first, possibly with some improvement, but no change in the field and no new hæmorrhages.

In June, 1890, six years later, Mr. O. returned greatly alarmed over the diminished sight in the remaining eye. He had had repeated attacks of transient dimness of vision, from which he would slowly recover, but the present attack was worse and persisted. He had no pain, with  $+2.50$ , V. =  $6/xviii$ , Tn (+?); pupil small, anterior chamber shallow, iris apparently healthy, cornea and deeper media clear; F. narrowed concentrically to  $26^{\circ}$ , and a notch out of the lower temporal field extending quite up to the fixation point. Pupil was too small to permit of satisfactory examination of the eye ground, so a drop of 4 per cent solution of cocaine was instilled. The dilation secured was but little. The fundus was found studded with numerous minute hæmorrhages, the arteries small, veins only relatively large, a doubtful cupping of the nerve, which is gray and obviously the subject of a slowly progressing atrophy. He was apprised of the fact that he had much cause for alarm in the presence of the optic-nerve atrophy, the retinal hæmorrhages, and his general dyscrasia. The arterial sclerosis had evidently advanced during the intervening years, and he was subject to fits of indigestion if he did not exercise care in eating. The portentous character of these retinal leaks was explained as showing the condition of the general blood-vessel system and warning him of the importance of moderate indulgence at the table and of a carefully regulated life. Blindness was pointed out as sooner or later inevitable, which he himself felt must be true after his experience with the other eye. Consultation was requested, but this he refused. Potassium iodide was administered and the instillation of eserine resumed. In a week vision rose to  $6/ix$ , and he said he could move about with less difficulty. The middle of July he went to the New England coast for the summer, and was not seen again until September 20. V. had fallen to  $6/xix$ . Field as before, and there were numerous flame-shaped hæmorrhages, with many red spots dotted over the fundus; he saw to get about with difficulty. His daughter related that he would pay no heed to his diet, was self-willed, and in spite of remonstrance would drink glass after glass of milk with an otherwise full and rich meal. Even at the seaside had worked incessantly at his business by telegram, correspondence, and otherwise. Consultation was again requested, but declined. Under purging, eserine, rest, and ascending doses of the iodide of potassium and corrosive sublimate his vision once more improved. October 11 V.  $6/ix$ , and the hæmorrhages were disappearing. His wife was then taken critically ill, which quite unnerved him, and his eye grew rapidly worse. A pronounced glaucoma now supervened; ball stony hard. His wife died at this very critical juncture, and after her burial the field was found contracted to central vision, and only the large letters on the test card could be made out by searching, at 2 or 3 feet. The pain, not severe at first in his stunned condition, steadily grew worse. That blindness was inevitable was only too plain, but at his request, and after carefully explaining that it was a forlorn hope, an iridectomy was successfully made upward, securing a typical and well-placed coloboma, notwithstanding the difficulties presented by the shallow anterior chamber. There was much bleeding, but the wound healed kindly and the tension was restored to normal, or possibly subnormal. There was no return of pain, but the eye remained red a long time and vision was slowly lost, probably from atrophy of the nerve or possibly from repeated hæmorrhages in the bottom of the eye.

He was last seen in April, 1891; then totally blind, free from pain, the eye nearly white, and the tension slightly subnormal. He came to reproach me with having been the occasion of his blindness, after a consultation had with another surgeon in a distant city, whose views he must have misunderstood. I can scarcely think it possible that any experienced surgeon would ever say that an eye with hæmorrhagic glaucoma had been lost through a colleague's neglect.

*Case 3.—Hæmorrhagic retinitis; secondary glaucoma; blindness.*—Mrs. X., æt. 70, was brought by her son, a physician, for rapidly failing vision in both eyes. Vision had sunk to 6 / xxx in O. D., and to counting fingers at 2 feet in O. S. She had no pain, but said her eyes were weak and had been failing her for a long time. The anterior perforating vessels were all dark-colored and large; the caruncles were swollen. There is no note regarding the state of the pupils or anterior chamber. O. D. media were transparent, and there were innumerable small hæmorrhages dotted over the fundus. The nerve margins were veiled; no cupping; marked perivasculitis. O. S. spicules of opacity in periphery of lens; details of fundus blurred by state of vitreous, but here also marked perivasculitis. No cupping of nerve; hæmorrhages in retina more numerous and larger, and involving macular region more seriously than in the right eye. There is no record of the field of vision. In both eyes the sclera are rigid. The patient was a tall, spare woman, with dark, opaque skin, iron-gray hair. Her manner was one of anxiety and distrust. There were gouty concretions in her finger joints, and the hands were distorted. Says she has suffered much from rheumatism. Urine had high Sp. Gr. and trace of albumin. Had been told her eye trouble was glaucoma, and her son brought her for an iridectomy. He was disappointed when a grave prognosis was given both as to general health and the probable results of any local treatment. Operation was advised against, and her general regimen carefully directed; potassium iodide was prescribed internally and eserine locally, while complete rest of the eyes and life in the open air were enjoined. The son was not satisfied with this conservative advice and sought the opinion of an eminent colleague in Philadelphia, who also advised against operative procedure. Still other opinions were sought until the desired advice was received and an iridectomy performed on the left eye after a very encouraging opinion had been given regarding the brilliancy of the results of iridectomy in glaucoma. The wound refused to heal; there was a succession of hæmorrhages into the anterior chamber, each time attended with pain. In this condition my advice was sought again, and the above history obtained; but I declined to direct them further, as they were making vows of vengeance against the doctor, who had probably mistaken the nature of the case, not being able to study the eye ground as I could do a month earlier in its history, and during the hæmorrhagic stage.

I am inclined to offer my excuse for calling attention to the gloomy clinical picture presented by hæmorrhagic glaucoma. I confess it would have been a more pleasing task to have invited the section to the consideration of some form of disease which experience has taught us to assail with some hope of a successful issue. The serious prognosis which must be given in this disease, however, makes it all the more important that ophthalmic surgeons should entertain more or less uniform views as to its essential gravity and its relation to other forms of eye disease in which increased intraocular tension is a characteristic symptom.

Inspired by the brilliant results of surgical procedure in primary glaucoma, the surgeon who has been fortunate enough to escape experience with this fortunately somewhat rare disease may be led into a too hopeful prognosis. It is important, therefore, that a line should be drawn, as definitely as may be, between hæmorrhagic and primary glaucoma, since on the one side lies a hopeful prognosis, while on the other both experience and pathology join hands to teach us the limits of our art. It was my purpose to make a careful study of the literature of this subject, but the recent excellent contribution of Bourgon has rendered that unnecessary. I must acknowledge my appreciation of the services rendered in this by Dr. A. G. Thomson.

My interesting, although forbidding, experience with this disease, the serious nature of which I did not at first fully appreciate, has prompted to a more careful study of the disease and to a comparison of my own experience with the published records. While this collective study has served to remove the tendency to self-reproach for the unfortunate outcome in the cases here reported, it is to be regretted

that it has also failed to inspire with greater courage or added hopefulness should further responsibilities arise.

*A comparatively rare affection.*—There is cause for congratulation, however, in the comparative infrequency of the disease. In 20,000 eye patients I have seen but 4 cases, and several of my colleagues with large experience report by letter that they have never met with a case. In 464 glaucomatous eyes reported by Knapp but 9 of them were classified as hæmorrhagic, and Bourgon, in his elaborate paper, places its occurrence at one case in 6,741 patients.

*Prognosis.*—It presents, however, a most gloomy picture, since, no matter what form of treatment is adopted after the glaucomatous stage of the disease is reached, it goes on to a fatal issue so far as vision is concerned. Thus, in 20 cases, comprising 24 eyes, all resulted in total loss of vision and 20 of the eyes were subsequently excised. The cases referred to are 1 by Norris, 1 by Kollock, 3 by Randolph, 2 by Nettleship, in all of which effort had been made to save the eyes. Then 1 each by Pagenstecher and Deutschmann, 2 by Brailey and Edmunds, and 2 by Bourgon, and 1 each by Wadsworth and De Schweinitz, in which enucleation was performed primarily. Bourgon, however, in detailing the results of iridectomy in 24 cases, records 16 failures and 11 enucleations. In reply to a private letter Wadsworth reports 1 case in which both eyes, with an interval of a few months, were the subject of this disease. The first eye was primarily excised and one had sclerotomy performed, which gave only temporary relief and was subsequently enucleated. Ayres also reports by letter 2 cases, one of which was enucleated after iridectomy had proved futile, and De Schweinitz 2 cases, 1 iridectomized and subsequently enucleated and 1 primarily excised. In the 3 cases here reported from my own private practice 4 eyes were involved, all proving fatal to vision, notwithstanding general therapeutics and operative measures in all. Two of the balls were enucleated and two passed from observation. It will be difficult to find a clinical picture with a darker background of prognosis than is here presented by hæmorrhagic glaucoma. The terse but unfavorable prognosis given in all our text-books are too well known to require repetition here.

Schweigger, e. g., states the general sense of classified treatises on diseases of the eye in the following language (Handbook of Oph., p. 52):

The results of iridectomy are generally unfavorable in those cases of secondary glaucoma which have developed after retinal hæmorrhages. In such cases vision is frequently greatly impaired by the hæmorrhages, and is irrevocably lost by the glaucomatous disease. But if severe and continuous pain remains, which yields to other treatment, nothing can be expected from iridectomy, and it only remains to enucleate the eye.

*Pathology.*—A grave prognosis, however, was to have been anticipated from a study of the general and local pathological conditions present in most of the patients who are the victims of this fell disease; so that, indeed, not only is vision surely lost, but the general prognosis is scarcely less grave than the local. While comparatively few deaths have found their reports in ophthalmological literature, it is nevertheless likely that in some cases the subsequently fatal ending would be known only to the general physician. The fact which is patent to us all, that of the numerous cases of retinal hæmorrhage we are called upon to treat a very small number ever develop glaucoma, is in a part at least accounted for by the fact that fatal apoplexies occur before the glaucoma has had time to develop, since it not infrequently happens that many months, and in some cases a year or even longer, may elapse between the occurrence of the retinal hæmorrhages and the onset of the glaucoma, in which time fatal intracranial apoplexies may and do occur. In other cases the results of treatment and an improved regimen may be effectual in restoring a more favorable state of health and by this means ward off both the glaucoma and the fatal apoplexy. That glaucoma does not follow most cases of

retinal hæmorrhage, or comes on only after prolonged intervals, may be due in part to the fact that hæmorrhages are more likely to occur at the beginning of the sclerosis of the vascular walls, as pointed out by Thoma and quoted by Bull, as follows:

In the beginning of the process there is a loss of elasticity of the vascular walls, shown in life by a soft, high pulse, and pulsation and tortuosity of the arteries, notably the arteries of the retina. At this stage there is the greatest danger of rupture of the arteries; later the vessels, by reason of the deposit of connective tissue in the intima become firm and rigid.

As the constitutional conditions upon which the retinal lesions depend, advance the general impairment of the nutritive processes increases in the eye as elsewhere. Under the irritating presence of the hæmorrhage in the retina and the disturbed nutrition of the eyeball, brought about by interference in its circulation, we recognize those conditions which readily lead to a disturbance of secretion and excretion, and probably pathological changes in the region of the canal of Schlemm. In the case reported by Norris (*Trans. Am. Oph. Soc.*, p. 476, Vol. iv) there were hæmorrhages in the sclerotic and in and around the canal of Schlemm.

Edmunds and Brailey (*Royal Oph. Hos. Reports*, Vol. ix, p. 380) point out that in pure glaucoma cases there is almost without exception a most important change in some or all of the intraocular blood vessels. This consists in a great enlargement of their caliber, consequent on their dilatation, and is accompanied in the majority of cases by a thinness of their walls, due to actual atrophy, and these changes are characteristic of glaucoma. In 17 cases of hæmorrhagic glaucoma microscopically examined by Edmunds and Brailey (*loc. cit.*) the arteries were found thickened in all but one. In Randolph's case (*Trans. Oph. Sec. Am. Med. Ass.*, 1891) there was found hyaline degeneration of the muscular coat of the central artery and the veins of the choroid enormously distended, while endarteritis was apparent in several of the smaller arteries. Bernbacher and Czermak always found in glaucomatous eyes the products of inflammation along the intraocular veins and around the veins of Schlemm's canal. Debrowolsky observed comparatively frequent periarteritis. Brailey (*loc. cit.*) says while arterial hypertrophy may be associated with general disease, as in Bright's, diabetes, or syphilis, it may also be a purely local affection, as in cases of glaucoma following injury where a similar condition of the blood vessels was found.

It is obvious, therefore, that the onset of glaucoma in apoplectic retinitis is determined by purely local conditions, which in certain cases is favored by a rigid sclera, or by retino-choroidal states brought about in hyperopic or astigmatic eyes, or by many other conceivable conditions, while in the absence of these favoring conditions the glaucoma may never occur; or may supervene only after the lapse of time, the irritating presence of the hæmorrhages, and the advancing pathological state of the blood vessels, steadily producing the local conditions shown to be characteristic of glaucoma. In a word, therefore, we must regard the glaucomatous symptom as secondary to the hæmorrhages, and more or less strictly dependent upon the accompanying local pathological states. The graver character of the glaucoma of the hæmorrhagic variety seems to grow out of its association with systemic conditions, of which it forms but a local expression.

Regarding the existence of general arterial disease many of the reports are silent. In my own cases they were all subjects of general arterial sclerosis, and in many of the reported cases the existence of general vascular disease is either distinctly noted, or the existence of albuminuria, sciatica, as in Randolph's case, or other symptoms of general disease were present, which rendered the existence of arterial disease highly probable. In two of my own cases the gradual progress of the general vascular disease was observed as the years went by. Both of these patients were victims of lithæmia and suffered repeated acute exacerbations of the accompanying digestive derangements, each time followed by an increase of the ocular

symptoms. In Dr. Wadsworth's case, however, he is careful to note the absence of any other than a local cause. The most recent and one of the most valuable contributions to the important rôle played by systemic disorders in causing ocular disease is a paper by Dr. Bull, read in July last, before the American Ophthalmological Society, on "Gouty retinitis, chorio-retinitis, and neuro-retinitis." Although there were retinal hæmorrhages in but one of the five cases upon which his paper is based, nevertheless, the eye ground changes described by him are much the same as those observed in hæmorrhagic retinitis, barring the presence of the hæmorrhages. This is especially true as regards the appearance of the blood vessels; namely, the white line along vessels, the result of peri-vasculitis or sclerosis.

The clinical facts connected with retinal hæmorrhages therefore justify the ophthalmic surgeon in the gravity of the prognosis given to patients who come with these lesions. In the case reported by W. F. Norris, which I also saw throughout its course, death followed from apoplexy one year after the eye had been enucleated. Von Graefe, Rampoldi, Brailey and Edmunds, Hirshberg, and others have observed cases of hæmorrhagic glaucoma followed by symptoms of intracranial hæmorrhage with a fatal issue, and Dr. J. A. White kindly reports by letter two cases of hæmorrhagic glaucoma, both of which died from apoplexy. This he puts forward as supporting his view that the whole trouble is due to atheroma of the arteries. We are therefore justified not only in giving a grave prognosis as to the loss of vision, but also as to a probable fatal issue.

In answer to a circular letter addressed to a few of my ophthalmological friends I have received the following replies. Dr. J. L. Thompson writes:

I have met with many cases of this disease, and in every instance have found that the glaucomatous symptoms were set up months and in some instances as long as two years after the hæmorrhages were first observed. I have watched these cases from time to time, some of them with marked impairment of vision, others with but slight, but without pain or increase of tension, for from six months to two years, but have eventually had to enucleate these eyes on account of the excessive pain. The long experience which has enabled me to watch these cases through all their phases has convinced me that hæmorrhagic glaucoma is a secondary affection in at least the great majority of instances. Eserine sometimes helps them for a short time. Iridectomy or sclerotomy are certainly contraindicated, but enucleation often has to be resorted to.

Dr. G. E. de Schweinitz writes:

It seems to me that hæmorrhagic glaucoma is always a secondary glaucoma, and no doubt depends, in the first place, on the hæmorrhagic retinitis which precedes it, and in the second place on the constitutional disturbance which determines the lesion in the retina. I have performed iridectomy on only one such case. Twenty-four hours after the iridectomy there was a fresh intraocular hæmorrhage and a prolapse of the vitreous into the wound. Curiously enough, after the abscission of this prolapse, the wound healed nicely and the patient was relieved from pain, although the eye was sightless. It seems to me that Bourgon's conclusion is a good one, namely; that during the hæmorrhagic period the general condition should be cared for and the ocular globe rendered as free from congestion as possible; during the period of confirmed glaucoma myotics are useful as well as moist heat. If surgical measures were called for, I would do either tapping of the vitreous or sclerotomy, but I would not perform iridectomy. I would do neither of these operations without previously obtaining the consent of the patient to perform enucleation if I failed, or if not enucleation, one of its substitutes. In a second case, which occurred only a few weeks ago, remarkable relief followed general medication, such as I have indicated, and, in addition, full doses of chloral, which I believe has some influence in lessening tension. In spite of this, however, there was a fresh attack at the end of a month, and the eye was enucleated at the patient's request, the eye being practically sightless. Microscopically the lesions were those of an exquisite example of hæmorrhagic retinitis.

Dr. F. C. Hotz refers to a published case (*Ophthalmic Record*, Vol. II, p. 234), and writes:

The affection I have no doubt begins in the retina; the glaucomatous symptoms are secondary, and no kind of operation will save the eye.

Dr. O. F. Wadsworth writes :

To obtain any definite idea of the etiology of hæmorrhagic glaucoma it must be shown why in some eyes hæmorrhage in the retina or vitreous is followed at greater or less interval by glaucomatous symptoms, in others not. In my opinion scarcely any approach has been made to the solution of this question. Probably the etiology is not always the same. Such a case as the following seems to preclude other than a local cause. A lady beyond middle life presented hæmorrhages scattered all over the retina of one eye ; in the course of the year, glaucoma and enucleation ; some months later sight of second eye lost with similar subjective symptoms ; eventually glaucoma ; sclerotomy, which helped for only a few days ; enucleation. Careful examination failed to discover disease of any other organ. The lady lived some twelve years from the time of hæmorrhage in the first eye and died of acute pneumonia. As to prognosis, it is generally fatal, not simply as to sight ; that is, as a rule, practically gone before the glaucoma appears ; but as to the existence of the organ. In rare cases pain and symptoms subside and do not recur ; usually enucleation is necessary to free the patient from continued pain. Both iridectomy and sclerotomy have failed in my hands to relieve pain for more than a very brief time. Still, if enucleation were specially repugnant to the patient I should try sclerotomy, but with the distinct understanding that it probably would have only a transitory effect.

Dr. Joseph A. White writes :

My opinion is, that the whole trouble is due to atheroma of the arteries. Two of my cases of hæmorrhagic glaucoma died of apoplexy, rather supporting the theory, because the eye and the brain are the places where the arteries are the most exposed, and liable to rupture.

Dr. S. C. Ayres says :

In relation to this disease I will say that I have been very fortunate in not meeting many such cases. The most striking case is that of a woman where the iridectomy was successfully done and I was called to her in a few hours, suffering intense pain. On removing the bandage I found the entire vitreous extruded and the globe partly filled with blood. I immediately enucleated the eye. In another case the globe partly filled with blood after iridectomy, and I think remained sensitive for a long time. In a severe case where the vision was lost, or nearly so, I should recommend enucleation. The after results of operation are so unsatisfactory that enucleation is frequently necessary even after well-executed iridectomy.

Dr. Swan M. Burnett speaks of it as a truly terrible disease, and regards himself fortunate in having seen but two cases.

Dr. Leartus Connor :

I have never seen a case of hæmorrhagic glaucoma in my own work, but have been led to regard the disease as primarily due to a degeneration of the blood vessels.

Dr. Edward Jackson reports two cases in which general therapeutic measures proved of value, but the ultimate results were not known. His feeling is against operation, but would operate if desired, after full explanation of the prospects, and decides in favor of posterior sclerotomy rather than iridectomy or anterior sclerotomy.

*Treatment.*—The views which have been expressed regarding the nature of hæmorrhagic glaucoma, together with the grave clinical picture which it presents, therefore fully justify a serious prognosis, not only as to the almost inevitable loss of vision and the sacrifice of the eye itself, but also to the possible fatal issue. My own judgment and experience are fully in accord with the recommendation of Bourgon (*loc. cit.*) regarding the treatment of the disease. Following his admirable clinical division we will discuss its treatment during the two characteristic periods it presents. First, a hæmorrhagic period ; second, a period of confirmed glaucoma. During the hæmorrhagic period our care must first be devoted to the general condition of the patient, and second to remove the congestion of the eyeball. No scheme could be better than this as a working therapeutic basis.

Our only hope for the preservation of any vision must be based upon our efforts

during the hæmorrhagic stage of the disease. Having in mind the fact that the majority of these cases are victims of general arterio-sclerosis, and the diathesis which has produced this state of the general vascular tree, the therapeutic measures to be adopted are such as are properly directed to the treatment of the existing diathesis, whatever it may be—gout, rheumatism, syphilis, morbus Brightii, diabetes, or chronic malarial disease, and the allied pathological states of the heart, liver, kidneys, or spleen. To this end the patient's daily life must be controlled. The hours for rest and the amount and kind of exercise and a carefully arranged dietary are of great importance. Potassium iodide and bromide, or in some cases iodide of iron, corrosive sublimate in small, frequently-repeated, and long-continued doses should be administered. In hæmorrhagic retinitis, with traces of albumin and granular or hyaline casts in the urine, I usually employ the Basham's mixture, with the corrosive sublimate added, and avoid the iodine salts. If the turgid state of the choroidal circulation is marked, and headache a prominent symptom, I have for many years employed ergot, often with much relief. If there is cause to suspect the existence of malarial poisoning, quinine should be given, either alone or with arsenic. In this connection the following case is of interest:

A lady, aet. 46, had recurring retinal hæmorrhages, extending over a year and a half, with now and again increase of tension and pain. The blood contained the corpuscles of Laveran, and she lived in a malarial region. The increased tension and pain were relieved by eserine and local bleeding and she received quinine and arsenic internally, and was sent to the seashore. The retinal hæmorrhages ceased to recur after six months, and she returned to her home in October. In November following she was attacked with apoplexy in church and died in a few days. Just one year before she had had a pronounced chill, the cold stage of intermittent, while sitting in the same seat. In this case the glaucoma was several times a threatening symptom, and it is fair to assume that the therapeutic measures adopted for her relief were effective in warding it off.

The general therapeutic measures which have been suggested are fortunately also well calculated to relieve the intraocular conditions. As we all know, the iodine salts and the bromide of potassium or lithium and bichloride of mercury are markedly beneficial in treating diseases of the chorioid and retina of the nonhæmorrhagic as well as the hæmorrhagic form. The value of ergot in these purely local affections is also well recognized; but in addition to these general measures certain local means are unquestionably of great value. In the first place absolute rest of both eyes is of great importance, and to this end, where refraction errors exist they should be carefully corrected, so that even in moving about all strain upon the fellow as well as the involved eye is removed. Plane smoked glasses should be worn to protect from glare of light. Plane glasses are preferable for the reason that the coquilles are usually irregular concave cylinders, and thus cause much irritating strain. Systematic local depletion is important. A single leech either to the temple or over the mastoid on alternate days, preferably before retiring at night. The local free use of a boric-acid wash, to which a very little cocaine may be added, not more than half a grain to the ounce, used with an eye cup rather than a pipette, is a grateful application, and removes the conjunctival irritation so often present. Even in the hæmorrhagic stage of the disease I esteem weak solutions of the sulphate or salicylate of eserine, not more than one-tenth of a grain to the ounce, instilled twice or thrice daily, of much value. I have long held the opinion that eserine was valuable because of its stimulating action over the muscular coat of the vessels, and I am gratified to note that this view is also suggested by Laqueur. Warm and moist applications favor congestion and should be forbidden.

*Period of confirmed glaucoma.*—Unfortunately the most painstaking and well-directed treatment of hæmorrhagic retinitis does not prevent the onset of glaucoma, and we are driven to a choice in the majority of cases between a primary enucleation of the eye and certain operative procedures, performed not in the hope of

restoring vision, for this is already hopelessly lost, but in the hope of saving the eyeball. We can readily believe that if general and local therapeutic means employed during the hæmorrhagic stage have failed to ward off the attack, they will be of little avail, after the onset of glaucoma is well established. In fact the excruciating pain is rarely relieved except by surgical procedure. Strong solutions of eserine, frequently repeated, local bleeding, and hot applications to the ball sometimes give partial but only transient relief.

Stilling (*Arch. Oph.*, Vol. 16, p. 445) recommends the use of chloral as having the property of reducing the tension of the ball, and De Schweinitz also recommends this drug for this purpose. The pain continuing, we are driven to surgical effort.

The result of operative measures for the preservation of either vision or the eyeball are extremely discouraging and, as has already been pointed out, in the great majority of cases the ball must be sacrificed to give permanent relief from pain. The gratifying results of iridectomy in ordinary glaucoma are not realized in this disease. Nevertheless, in case I it gave marked relief, which might have endured but for the unfortunate attack of cholera morbus. In the second eye of case II, although blindness was not averted, it nevertheless gave permanent relief from increased tension and pain, and the eyeball was preserved. The same was true of one case each, reported by Ayres and De Schweinitz. In a few other cases the ball was retained, presumably as the result of iridectomy. Notwithstanding this, the consensus of opinion is opposed to iridectomy. On this point, however, there is a diversity of opinion, and I can not entirely agree with the view of Bourgon that it should be vigorously prescribed. Paracentesis of the cornea in case I gave complete relief from pain, which lasted several days, and therefore commends itself as a simple measure for temporary relief until other and more radical means may be adopted. Sclerotomy at the rim of the anterior chamber seems on the whole to commend itself as superior to iridectomy, a fact to have been anticipated, having in mind the general vascular disease. After a careful study, should future responsibilities arise, I should first of all do sclerotomy or paracentesis of the vitreous chamber and, having by this means relieved the tension of the globe and possibly secured a deeper anterior chamber, perform either a free anterior sclerotomy or, if the iris were moderately healthy, a broad iridectomy.

#### DISCUSSION.

Dr. CHISOLM. Our general experience fully sustains the opinion that hæmorrhagic glaucoma is the most destructive of eye troubles and least amenable to surgical or medical treatment. In my earlier career when I attempted to allay the pain by iridectomy I had the misfortune of inducing a rupture of retinal vessels and a destruction of the eye speedily by panophthalmitis. In such cases now shun operative procedure. I have, in the midst of the general fatality had one good result from iridectomy in hæmorrhagic glaucoma. A gentleman, aged 73, first consulted me in 1873. I found slight bending of vessels and a hæmorrhage near the disk. He was myopic. I gave him strychnine  $\frac{1}{20}$  gr. three times a day, and used eserine 1 grain to 1 ounce morning and evening. From time to time I saw him. He did not live in Baltimore. The eserine kept the eye quiet, and the strychnine was a good tonic. He kept up this treatment for two years. In the meantime the hæmorrhage had quite disappeared and vision had not materially deteriorated. He had  $\frac{15}{20}$ , and could be improved by glasses. He was becoming restless under the daily use of the medication and requested operation. He had been all his life a bookworm and had posted himself about his disease. He knew all that the books contained about the value of iridectomy, which he desired me

to perform. The operation was satisfactory. In the course of time I adjusted glasses and lost sight of him. Three weeks since I received a letter from him with this statement: "I feel it my duty to state to you the result of your operation. The operated eye is now as serviceable as it was when you operated on it, but the one not operated on, which was then the best, is now totally useless."

Dr. WOLFE. I have listened with much pleasure to Dr. Risley's interesting paper. I was particularly pleased with the remarks referring to the etiology of hæmorrhagic glaucoma, as they remind us that not all eye troubles are to be traced to errors of refraction. A considerable number of hæmorrhagic as well as the other forms of glaucoma are caused by mental emotion. A widow who had suffered grief and anxiety in nursing her husband, a mother who has been mourning the loss of a child, a gentleman who has met with heavy losses in business; all mental distress may produce glaucoma in persons whose nervous and vascular systems predispose them to eye affections. The urinary secretions should be attended to; they generally indicate malnutrition and derangement of the organism. In addition to uric acid we sometimes find some traces of sugar. With regard to the question of operative interference I am guided by the physiognomy of the eye. With a moderate anterior chamber and the iris not quite atrophied I perform a large iridectomy, not with any sanguine hope of giving vision, but to save enucleation, which I very much dislike. I prefer in extreme cases the puncture of the sclerotic and allowing the escape of a very little of the vitreous. Of course a great deal depends upon the stage when the case comes before us.

Dr. HUBBELL, of Buffalo, N. Y. Dr. Risley's paper has been to me a very interesting one and his experience is another proof of the inefficiency of treatment to save vision and prevent suffering in hæmorrhagic glaucoma. He has again demonstrated that the prognosis is unfavorable and the only means of relief is enucleation. I have had two cases, both occurring in the advanced stages of the disease, and the radical treatment was at once resorted to. There appears to be little doubt as to the pathology of the disease, being a general arterio-sclerosis in which the vessels of the eye participate. The histological studies of Valude, of Paris, which I had the pleasure of presenting to the English-speaking profession in a translation published recently in the Ophthalmic Record, together with those of others, seem to establish this fact. Yet I ask why it is that hæmorrhagic glaucoma, as in Valude's cases, Dr. Risley's, my own, and those of others, is so frequently monolateral? The case which the president of our section has cited seems to me not to belong to the class under discussion. We must distinguish between hæmorrhagic and ordinary glaucoma, with accidental retinal hæmorrhages, and between hæmorrhagic glaucoma and hæmorrhagic retinitis, with possibly an incidental increase of tension. While we all have the highest regard for Dr. Chisolm's skill in diagnosis, yet is it not possible that his case was one of ordinary glaucoma, with retinal hæmorrhage, and not typical hæmorrhagic glaucoma at all? If it was not hæmorrhagic glaucoma proper, then it does not cast any doubt upon the position which I hold, viz., that this disease is fatal to vision and that palliative and tentative treatment is of no avail.

Dr. RISLEY, in closing the discussion, said he had been much interested in the case reported by Dr. Chisolm. If we were to accept it as a case of hæmorrhagic glaucoma its history offers an excellent demonstration of the fact quoted in this paper from Thoma that in the beginning of the arterio-sclerosis hæmorrhages were more likely to occur; that as time goes on the vessel walls were strengthened by the connective tissue produced in the retina. The operation was performed long after the hæmorrhages were first noted, and during this time this strengthening of the blood vessels may have taken place, thus affording an admirable illustration of nature's conservatism. Certainly the hæmorrhage had ceased at the time of the operation. Since, however, when first seen the case was regarded as one of glau-

coma with hæmorrhages, and not apoplectic retinitis, he feared it could not be included in the group under discussion. Much as he would welcome even one case of cure of hæmorrhagic glaucoma, certainly cured by any means, he thought that Dr. Chisolm's case must be placed in a group with primary glaucoma. He was glad to hear Dr. Wolfe's remarks regarding the important effect of the emotions, grief and disappointment particularly, in the etiology of glaucoma. This was especially demonstrated in the cases reported. He felt, however, that this result was produced by the disturbance of nutrition under the depressing influence of grief. All were familiar with attacks of jaundice and digestive derangements consequent upon these depressing influences. In a word, the blood stream became loaded with poisonous products, which in turn set up or aggravate the intraocular conditions characteristic of glaucoma, especially in eyes where glaucoma was imminent.

In reply to Dr. Hubbell he would say that the disease was by no means a monocular disease. In the 20 cases collected in the paper, in 4 of them, or 20 per cent, the disease was binocular.

---

#### A COMPARISON OF THE EYES OF WHITE AND COLORED PUPILS IN THE PUBLIC SCHOOLS OF WASHINGTON, D. C.

By E. OLIVER BELT, M. D., of Washington, D. C.

By numerous examinations made in the schools of this country and of Europe it has been found that comparatively few children are nearsighted when they first begin school, but at the end of school life a large percentage have this defect. According to a paper on the subject by Dr. S. D. Risley, of Philadelphia, in an examination by Drs. Loring and Derby of the eyes of 1,133 school children in the city of New York, 3.55 per cent were found to be myopic at 7 years of age, while at 20 years 26.79 per cent were nearsighted. In St. Petersburg, Prof. Erismann found, in 4,538 pupils, 13.6 per cent of myopia in the primary and 42.8 per cent in the higher classes. In Germany the rise was from 11.1 per cent to 52.1 per cent. The fact of this increase of nearsightedness during school life being established, the important point for the physician to consider is its cause and its prevention. It is also found that hypermetropic eyes are most common in the primary grades, and there is a marked decrease in this defect by the end of school life, while the percentage of eyes with normal refraction remains about the same throughout the different grades.

Now, are the eyes which become nearsighted, those which were normal, or are the farsighted eyes unhealthy ones, and do they change their refraction to normal and then continue to change until they become myopic? These are questions which should be determined if we wish to prevent these increasing defects. That heredity and older civilization have much to do with the frequency of myopia would seem to be indicated from comparisons made between pupils in Europe and this country. And I have thought a comparison between the eyes of white and colored children would throw additional light upon this point. Whether there is a tendency for hypermetropic eyes to become myopic could only be determined by examination of the same pupils for a series of years through different grades. With these objects in view I applied to Prof. W. B. Powell, superintendent of the public schools, Washington, D. C., for the purpose of making examinations among children in the public schools. Prof. Powell at once took a deep interest in the investigation, and gave me permission to examine as many pupils as I desired in both white and colored schools.

This report is a summary of results found in the Grant school, which is composed of white pupils, and in the Mott school, which is composed of colored pupils. Mr. S. M. Ryder, principal of the Grant school, and Dr. W. B. Evans, of the Mott

school, took an active interest in the matter and gave me valuable assistance, especially in securing consent of the parents for the examination.

Four hundred and twenty pupils were examined, 210 from each school, 15 boys and 15 girls from each grade except the first. Their ages ranged from 6 to 17 years. All defects were noted, cases of myopic astigmatism were placed under the heading of myopia, and hypermetropic astigmatism under hypermetropia. The refraction was tested with lenses and by retinoscopy. There was only 1 case of color-blindness in each school, less than 0.005 per cent, and each case was among the boys.

By most authors the usual percentage of color-blindness is from 0.03 to 0.05 per cent among males, and less than 0.01 per cent among females. I am informed by Prof. Powell that the pupils in the public schools here are taught the colors, so this lessened the possibility of color ignorance being mistaken for color-blindness.

There were only 4 cases of amblyopia, and all were among white girls. There were 10 diseased eyes in the white school and 4 in the colored school, aside from errors of refraction and cases of conus. There were 5 cases of choroidal atrophy in the white and 1 in the colored. There were 4 cases of corneal opacity in the white and 2 in the colored, and there was 1 cataract in each. There was 6 cases of strabismus in each. In the white 3 cases were internal and 3 external; in the colored 1 case was internal and 5 external. Conus or pigment about the disk was found in 15 per cent of the cases of emmetropia in the white, and 13 per cent in the colored; in 21 per cent of the cases of hypermetropia in the white, and 18 per cent in the colored; and in 16 per cent in the cases of myopia in the white, and 15 per cent in the colored. In the total number of cases of conus there was an increase of only  $0.02\frac{2}{3}$  per cent from the three lower to the three higher grades in the white, and of  $0.03\frac{3}{5}$  per cent in the colored. Conus is thought by many to be an indication of error or change of refraction, and though there can be no question about its meaning in errors of high degree, it seems to me very doubtful whether slight pigmentation about the disk is always pathological. Normal acuteness of vision was found in 80 per cent of the white boys and 94 per cent of the colored boys, and in 68 per cent of the white girls and in 86 per cent of the colored girls.

The following was found to be the average refraction :

|             | Emmetropic.      |                  | Hypermetropic.   |                  | Myopic.          |                  |
|-------------|------------------|------------------|------------------|------------------|------------------|------------------|
|             | White.           | Colored.         | White.           | Colored.         | White.           | Colored.         |
|             | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> |
| Boys.....   | 0.71             | 0.80             | 0.16             | 0.15             | 0.12             | 0.04             |
| Girls.....  | .49              | .73              | .31              | .18              | .19              | .08              |
| Total ..... | .60              | .76              | .23              | .16              | .16              | .06              |

The number of pupils examined was too small to get a correct idea of the decrease of hypermetropia and the increase of myopia from a comparison of the lowest with the highest grade. But by comparing the three lower with the three higher grades we can form an estimate of the changes during school life.

The averages were as follows:

|                           | Emmetropic.      |                  | Hypermetropic.   |                  | Myopic.          |                  |
|---------------------------|------------------|------------------|------------------|------------------|------------------|------------------|
|                           | White.           | Colored.         | White.           | Colored.         | White.           | Colored.         |
|                           | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> | <i>Per cent.</i> |
| Three higher grades.....  | 0.60             | 0.71             | 0.17             | 0.16             | 0.23             | 0.12             |
| Three lower grades.....   | .59              | .83              | .31              | .16              | .10              | .01              |
| Increase or decrease..... | +.01             | -.12             | -.14             | -.00             | +.13             | -.11             |

This shows that the percentage of eyes with normal refraction remained about the same in the white and decreased 0.11 per cent in the colored schools. While there was a decrease in hypermetropic eyes from 0.31 to 0.17 per cent in the white, the colored remained about the same, and there was an increase of myopic eyes from 0.10 to 0.23 per cent in the white, and from 0.01 to 0.12 per cent in the colored. Errors of 0.05 D. or less were not noted, except in cases of astigmatism, from a belief that it is often impossible to determine errors that slight without a mydriatic, hence the percentage of hypermetropia is not as high as found by some observers. The refraction found by me, however, corresponds closely with the average found by different observers in 160,000 eyes examined, which was as follows: Emmetropic, 58.8 per cent; hypermetropic, 21.9 per cent; myopic, 19.5 per cent. These figures are from a paper by Dr. B. Alex. Randall, of Philadelphia, to whom I am indebted for some valuable suggestions in reference to the investigation. In the following table I give the changes in refraction from the beginning to the close of school life among pupils in several cities:

| Examined by—                   | Emmetropic. |        |                         | Hypermetropic. |        |                         | Myopic.     |        |                         |

The percentage of hypermetropia of 1 D. and over was 0.078 in the white, and 0.066 in the colored; and of myopia was 0.026 in the white, and 0.023 in the colored, while the astigmatism of all degrees was 0.25 per cent in the white and only 0.10 per cent in the colored. These statistics seem to indicate that hypermetropia and myopia of high degrees are nearly as common in one race as in the other, and may be due to malformation of the eyeball, independent of race or civilization; but that slight error, and especially astigmatism, are more commonly the result of abuse of the eyes, as found in a higher civilization.

Refraction error of 1 D. and above.

CONCLUSIONS.

First, that children often have defective eyes without being aware of it, and are loth to complain of their troubles, as shown from the fact that although 40 per cent had defects which cause more or less discomfort, only 0.15 per cent complained of headache or of their eyes becoming tired or painful upon use. These

children, however, frequently give evidence of trouble by not advancing as rapidly in their studies as others of their age and too frequently are thought to be stupid when in fact their eyes are at fault. This is well illustrated in the second grade, in which most of the pupils are 7 or 8 years of age; there were some, however, still in the second grade who were 10 and 11 years of age, 80 per cent of whom had defective eyes, which was evidently the cause of their backwardness.

Second, the increase of nearsightedness among Washington school children is less than in most American cities, probably because their physical condition is better when they begin school. There is less poverty here. A smaller number live in overcrowded tenement houses, and their hygienic surroundings are generally better. The school buildings are well lighted and ventilated and the seats are arranged so they will not face the light. In some, though, the blackboards are placed between the windows, which is not to be commended. I am informed by Prof. Powell that close application for any length of time is not required of children in the lower grades, much of their teaching at this period being by object lessons. This is a most important point, for at this age the eyes are most easily injured. I think authorities agree with Dr. Risley, who says "the probability of harm resulting from the school life diminishes with every added year of age, in all states of refraction;" however, the marked increase of myopia between the ages of 14 and 16 years would indicate that the time of puberty is a critical one for the eyes.

Third, the few cases of abnormal eyes found among the colored pupils, as compared with the white, indicate the influence of the more advanced civilization in the causation of defective eyes. Especially is this so of astigmatism, which was found in 0.25 per cent of the white and in only 0.10 per cent of the colored pupils. Heredity also has much to do with it. Myopes should not marry myopes, and parents with eye trouble should especially be careful to see that their children's eyes have proper attention in order that they may avoid the development of the same defects.

Fourth, that hypermetropic eyes are unhealthy ones and tend to become myopic after passing through the stage of emmetropia would seem to be indicated by the facts that the decrease in hypermetropic eyes in the white school, which was 0.14 per cent, corresponds closely with the increase of myopia, which was 0.13 per cent, and the greater the percentage of hypermetropia at the beginning, the more myopia at the close; e. g., in the white school there was 0.31 per cent of H. at the beginning and 0.23 per cent of M. at the close, while in the colored school there was only 0.16 per cent of H. at the beginning and only 0.12 per cent of M. at the close. These facts being established it follows that correction of hypermetropia at an early age would probably prevent the development of many cases of myopia during school life.

# FURTHER STUDIES OF THE CYCLOPLEGIC VALUE OF HOMATROPINE AND COCAINE DISKS, AS ATROPINE, DUBOISINE, AND HYOSCINE SUBSTITUTES.

By CASEY A. WOOD, C. M., M. D.,

*Ophthalmic Surgeon Alescian Hospital, Oculist and Aurist Cook County Hospital and to the Emergency Hospital, Chicago Post Graduate Medical School.*

Nearly three years ago, in an article contributed to the American Journal of Ophthalmology, I gave the results of some experiments I had made with mixtures of homatropine and cocaine, and with solutions of atropine and duboisine, for the purpose of comparing their relative merits as cycloplegics. The conclusions I then arrived at were these:

(1) In the shape of watery solutions probably less than 10 per cent of the dissolved alkaloid becomes absorbed in such a way as to affect the eye, the remaining 90 per cent being carried off into the nasal duct or flowing over the cheek with the tears.

(2) Mixtures prepared with vaseline, sanitas jelly, lanolin, and similar menstrua, or, as in Lang and Barrett's\* experiments, castor oil, are much longer retained in the conjunctival sack. The drugs thus longer kept in contact with the ocular and palpebral surfaces undergo, as Green suggests, a much more extensive absorption and produce a still more pronounced effect.

(3) They are absorbed by the blood vessels and other absorbents of the cornea and conjunctiva, and not by those of the nose and throat. But such oily and greasy mixtures have this serious drawback: They leave a thin film upon the corneal surface which interferes with the examination of the eye, especially when one wishes to determine the refractive condition.

(4) The form of gelatin lamellæ or disks appear to be the most useful one in which to apply agents to the eye for the purpose of securing their fullest mydriatic and cycloplegic action. These undergo a slow, regular, and complete absorption when put into the conjunctival sack.

(5) The addition of cocaine to almost all the alkaloids used in ophthalmic practice undoubtedly increases their peculiar effects. (See also the reports of Malakoff and the experiments of Lang and Barrett beforementioned.)

(6) From the foregoing results, and after much experimentation on the subject, I concluded that the most decided cycloplegic effects of homatropine are obtainable from its employment in the gelatin disk form, associated with cocaine. In its most convenient and stable shape these disks can not be made to hold more than gr.  $\frac{1}{25}$  of these alkaloids, hence I was necessarily restricted to the use of gr.  $\frac{1}{50}$  each Merck's homatropine and cocaine.

Since the publication of my original paper I have not lost sight of the purpose I originally had in view, viz, the attempt to find some cycloplegic less objectionable than atropine for the measuring of refractive errors. I happen to be a firm believer in the doctrine that it is necessary to know the absolute refractive condition before one can intelligently prescribe glasses, and I further believe that it is requisite to paralyze the accommodation as the best means of obtaining the information in the majority of cases under, and in some cases over, 40 years of age. For the past year I have been engaged in this line with the gelatin disks aforesaid, with disks containing gr.  $\frac{1}{25}$  of homatropine alone, and with various solutions in water tropacocaine, homatropine plus cocaine, duboisine sulphate, atropine sulphate, hyoscine hydrobromate, and hyoscyamine sulphate. Without troubling you with details, I may say briefly that for the determination of the refractive condition, and with the idea of making the conditions of the comparative test

\* Lang and Barrett: The Action of Myotics and Mydriatics. Oph. Hos. Reports, Vol. XI, 130 and 219.

as constant as possible, I chose those patients in whom I could employ a number of agents at proper intervals, and whose refractive state would be most likely to afford reliable tests. These were put under the influence of the particular cycloplegic and their refractive state determined by retinoscopy. Every case was carefully worked out by my assistant, Dr. T. A. Woodruff, who is an expert skio-scopist. Sometimes one agent was used first, sometimes another, but in every instance the effect of the previous cycloplegic was allowed to pass off before the second was employed. Using all possible care to avoid sources of error, the refraction of 34 selected eyes, furnishing 68 principal meridia, was thus determined. The results I have here drawn up in chart form.

| Number. | Atropine. | Hyoscine. | H. and C. discs. | Number. | Atropine. | Hyoscine. | H. and C. discs. |

In these observations (166 in all) 2 drops of 1 per cent solution of atropine sulphate were dropped in each eye 3 times daily, after meals, for 2 days, and the examination made in from 1 to 3 hours after the last instillation. Of the hyoscine and hyoscyamine 2 drops of a 4-grain solution were instilled into each eye 3 times at intervals of 20 minutes, and the examination made in from 1 to 2 hours after the last dose. The disks were employed as hereafter described. Every precaution was taken to prevent poisoning by the hyoscine and the disks were used for the examination of the same meridia in 30 instances. In 16 of these the refraction was exactly the same, or the highest differed from the lowest not more than 0.25 D. In 10 instances the difference was 0.50 D. In only 2 instances out of the 30 was there a greater difference than 0.50 D., a case to be afterwards referred to. In these 30 cases atropine showed the highest refraction or was one of the highest in 19 instances; hyoscine in 22 instances, and homatropine and cocaine disks in 15 instances. Coming now to the tests of atropine and H. & C. disks we found that they were the same, or did not vary more than 0.25 D. in 58 out of 68 meridia. Of the remaining 10 the result varied 0.50 D. in 8 cases, and in 2 instances there was a radical difference, to be again referred to. Speaking generally, atropine showed a higher refractive condition than the disk in 21 out of the 68 cases, while the disks showed an increased refraction over atropia in 4 instances. In a single instance of mixed astigmatism, before referred to, did the refraction of 2 principal meridia

amount to more than 0.50 D., viz, 0.75 D. and 1.75 D. greater in the case of atropine than that shown by the disks. In this case the disks were first used. That this may happen in a second trial of any cycloplegic, in relieving a spasm of the accommodation, is well known. I have recently had a case which well illustrated this fact, where a second trial with atropine showed a much greater difference. A boy, aged 16, with marked astigmatism in each eye was atropinized in the usual way with 1 per cent solution, and the skioscopy and result was 2.75 D., 3.25 D., 2.50 D., 3.25 D. A week later he was found to have with full correction nearly in either eye. My suspicion being aroused by this early acceptance of his glasses I again atropinized his eyes and the result was +4 D. and +4.75 D., +4.50 D. and +5.25 D., i. e., an advance of between 1.25 D. and 2.00 D. in the 4 meridia. Ten days afterwards he obtained  $V.=\frac{6}{6}$  — in either eye. A month afterwards his V. in each eye was  $\frac{6}{6}$  + with all symptoms relieved.

As a result of these and other experiments I have reached the following conclusions, some of which are modifications of the propositions contained in my first article:

(1) If two gelatine disks containing gr.  $\frac{1}{50}$  each of homatropine and cocaine be placed in the conjunctival sac at an interval of 20 minutes, the eye being all the while kept closed, the ciliary muscle will in most instances be found to be fully paralyzed in from 70 to 100 minutes after the introduction of the first disk.

(2) In persons under 25 years old, or whenever ciliary spasm is suspected, the best results are obtained by the use in another 20 minutes of a third disk or one containing gr.  $\frac{1}{25}$  of homatropine alone, the examination in that case being best made between 90 and 120 minutes after using the disk. The first two disks containing cocaine are sufficient to furnish the chief advantage which, in my opinion, resides in that alkaloid, viz, of increasing the absorbing powers of the cornea for agents combined with it, while the increased dose of homatropine produces a more thorough relaxation of the ciliary muscles. An eserine disk (gr.  $\frac{1}{1000}$ ) inserted the following morning will enable the patient to do near work within an hour or two. (3) The disk should be inserted in the eye on the tip of a damp camel's hair brush and should always be applied to the ocular conjunctiva at its inferior and outer surface, the patient looking up and in while the lower lid is drawn down. Any adherent or sticky gelatine may be easily wiped off the palpebral edges with a damp cloth or a piece of wet absorbent cotton.

In my preference for these disks over any solution of atropine I wish to state that I do so only on the grounds of the quicker and more evanescent cycloplegic action of the former. I always use atropine whenever I possibly can, and particularly if in my judgment the patient would be benefited by ciliary rest, as many of our cases are. But for the business man, the clerk, the bookkeeper, the lawyer, the doctor, the school-teacher, *et hoc genus omne*, ten days of ciliary or any other kind of rest is usually impossible. It is with them either an examination for glasses of the optician and jewelry store order or a transient cycloplegia.

In the list of dangerous cycloplegics I would place duboisine, hyoscine, and hyoscyamine. They are all, especially the last two, much prompter and more fiercely active cycloplegics than atropine or these disks. If hyoscine and hyoscyamine are used in solution and in doses strong enough to insure ciliary paresis, i. e., in disks somewhat less than atropine and duboisine, they are certain to produce toxic symptoms more or less pronounced in about one-quarter of the cases. If used at all they should be instilled in the oculist's office, and in my experiments I found this to be the only safe plan to pursue. If this be done, the refractive condition can be readily determined in one day, the ciliary paresis passing off in from 72 to 96 hours. Upon their cycloplegic action single disks of eserine have little or no permanent effect. Tropacocaine has, so far as my experiments went, no cycloplegic advantages over cocaine, while its mydriatic action seemed to me to be less than that of cocaine.

THE NECESSITY FOR COMPLETE SUSPENSION OF ACCOMMODATION  
BY MYDRIATICS IN THE ADJUSTMENT OF GLASSES.

By G. C. SAVAGE, M. D.,

*Professor of Ophthalmology, University of Nashville and Vanderbilt University, Nashville, Tenn.*

If the accommodation could be suspended instantaneously and then, after the work of refraction has been accomplished, could it be as speedily restored to the normal, who and where is the oculist who would not exercise such magical power in all his cases of refraction? If the exercise of this supposed magical power would be justifiable, then there must be some strong reasons for using the means, really at our command, for putting at rest the ciliary muscle when a focal error, whatever may be its nature, is to be corrected. It is the object of this paper to give the reasons that not only justify but actually demand the use of the mydriatic in refractive work. In presenting the numerous reasons for the use of the mydriatic in the work of refraction all the reasons against its use will be met. While in some cases glasses may be prescribed simply to sharpen vision, it must be confessed that the greater number of cases coming under the observation of the oculist are persons who suffer because of strain. This leads us to inquire, what is eye-strain? A clear understanding of what the answer to this question should be will go far toward settling the question of the proper line of practice intended for its relief.

None will controvert the statement that eye strain is muscle strain, and that the muscles concerned in the visual act are; first, those regulating the quantity of light admitted into the eye and the direction of its rays, these are the two sets of fibers in the iris, and the ciliary muscle; second, the extrinsic muscles, the recti and the obliqui, which are concerned in directing the visual axes and in keeping the naturally vertical meridians of the corneæ so related that images may fall on corresponding parts of the two retinae. Muscular action is not muscle strain, unless the action is either too prolonged or too great for the inherent power of the muscle. Some, by their teaching, would show that only the ciliary muscle is susceptible of strain, and that ciliary strain alone is capable of bringing into existence that long train of nervous phenomena with which the oculist and, of late years, the neurologist are so well acquainted. There are others who are accused of believing and teaching that the extrinsic muscles are alone susceptible of that fatigue which brings discomfort, in varied forms, to our patients. There are not a few, however, whose practice is governed by the sounder doctrine that both the intrinsic and extrinsic eye muscles may be put to the necessity of doing more work than their strength will bear, and that the consequent strain, whether in the one set or in the other, or in both at the same time, will develop headache, vertigo, confusion of thought and a host of other phenomena. While glasses prescribed for the correction of focal errors were once thought capable of curing all symptoms dependent on eye strain, the time is now when no such claim can be sustained. Lenses that give a perfect correction of existing focal errors may, in some instances, augment rather than allay the suffering due to eye strain. Such patients would be better without lenses until the chief cause of suffering, in the individual case, has been found and, by the proper treatment, cured. But I am not one to cry out against the prescribing of glasses. My wearing lenses is sufficient evidence of my regard for and my appreciation of them. Properly determined, scientifically prescribed, and correctly worn, they do only good. But in prescribing glasses we must take into consideration both the focal error and the muscular adjustment, particularly the adjustment of the internal and external recti. Since glasses can do more than relieve ciliary strain; they can, if properly selected, relieve strain of the internal and external recti independent of pris-

matic effect;\* also strain of the oblique muscles in cases of oblique astigmatism; they should be scientifically prescribed, after a most painstaking study of the focal error and the muscular adjustment.

For the present, fixing our attention on focal errors, we find that there are these: myopia, hypermetropia, and the several kinds of astigmatism. In emmetropic eyes there is no strain, in the proper sense, when used in moderation. In simple myopia of 3 D. or more the ciliary muscle is never called into action and, therefore, can never be strained. If such eyes give annoyance, other than dimness of distant vision, the cause must be sought, and will be found in the relationship of the extrinsic muscles. In simple hypermetropia the ciliary muscle, during waking hours, is ever acting until quieted by age. Any action of the ciliary muscle for sharpening distant vision is strain, and in such eyes overaction (strain) is necessary in order to good near vision. In some of these cases the ciliary muscle is hyperdeveloped, the center controlling it has an abundant supply of nerve force and there are no symptoms resulting from the strain. Other hypermetropes are not so fortunately constituted, and the ciliary strain, caused by the refractive error, is felt in some form or other.

In astigmatism, of whatever kind, with the principal meridians in the vertical and horizontal, or if oblique the obliquity is in the same direction and at the same angle in the two eyes, the astigmatic refraction also being equal in the two eyes, there is ciliary strain directed against this refractive error. As to the character of the effort made by the ciliary muscle there is some difference of opinion. Whatever may be the nature of this strain it is capable of correcting wholly only the lower degrees of astigmatism, and only a small part of the higher degrees of this error; but that the effort is being continually made for distant and near vision, in cases of hypermetropic and mixed astigmatism, also in myopic astigmatism, when near vision is attempted, there can be no doubt. This effort is strain if the action is equal and simultaneous in all parts, holding the focal interval on the retina, or adjusting the rays of first one principal meridian and then those of the other, as vertical or horizontal lines may be viewed; it is strain if the ciliary muscle acts, as described by Martin, in sections the one opposite the other, thus, by altering curvature, developing a lenticular astigmatism correcting in whole or in part the corneal; it is also strain if the longitudinal fibers of Bowman are alone concerned in the effort of correcting the astigmatism by tilting the lens on an axis in a plane with the corneal meridian of greatest refraction, thus producing a lenticular astigmatism counteracting to some extent the corneal. In oblique astigmatism, as usually encountered, there is demonstrable necessity for action (strain) on the part of the obliques,† which, in these cases, is a factor added to the ciliary strain excited by the astigmatism. The strain caused by astigmatism is nearly always a source of annoyance to the patient and should, in all cases, be fully corrected, regardless of any and all other conditions.

Ciliary strain is an effort on the part of the ciliary muscle to increase the refractive power of the lens, as in hypermetropia, or to render it astigmatic, by tilting or otherwise, for the correction of a corneal astigmatism. This action, or these actions, of the ciliary muscle is from necessity brought into existence in very early life, and because of daily repetition becomes a fixed habit of the muscle, a habit whose existence continues in nearly all cases for a time after the cause for it has been taken away by properly adjusted lenses. If this is true who knows that his work has been correctly done, when he undertakes the correction of a refractive error while the ciliary muscle is allowed to continue at its old work? That glasses thus fitted often (for a time) give satisfaction is but a verification of the old adage that "guesswork is as good as any when it hits."

\* See Ophthalmic Record, No. 11, vol. 2.

† See Ophthalmic Record No. 1, vol. 1.

How often do we find ourselves declaring what is a truth, that ophthalmology is more nearly a pure science than any other department of medicine? And is not this true mainly because of our perfect knowledge of the refraction of the eye and the conditions that result from errors of refraction? If there were no modifying conditions nothing could be more scientific than the full correction of errors of refraction, which could not be done accurately without first putting at rest the self-correcting power, the ciliary muscle. Since these modifying conditions are known and can be removed, it is the plain duty of every oculist to determine, by a most thorough and painstaking examination under the only favorable condition, suspension of accommodation, what the refractive errors are, even though, because of the existence of some known muscle error, he might know that it would not be proper to give fully correcting lenses at that time; for having cured the muscle error his record would enable him later to give the full focal correction. There is no condition of the extrinsic muscles which would be disturbed by a full correction of any astigmatic error; there is no astigmatic error which may not be partly concealed by ciliary strain.

In the work of refraction how fortunate for science and practice, for patient and practitioner, that we have at our command mydriatics, whose effect is to temporarily suspend the self-adjusting power of the faulty eye, during which period artificial correcting means may be accurately determined. While a mydriatic does not, in the least, interfere with any of our objective methods of examination, it gives greater accuracy to most of these. All must confess that the ophthalmoscope can measure more correctly the refractive error of an eye, when under the influence of a mydriatic than when it is not. The man most skilled in estimating the refraction of eyes by means of the ophthalmoscope must confess that it took both time and practice to enable him to voluntarily suspend his accommodation, with his eye on the dark side of the instrument; then how can he expect the patient, whose eye is on the light side of the instrument, to learn in a minute to suspend an involuntary power, one that is being stimulated into activity by the light that is thrown on the retina? When there is forced suspension of accommodation (by a mydriatic) in the patient's eye and acquired suspension of accommodation (by practice) in the observer's eye, then there can be some degree of accuracy in the measurements of the ophthalmoscope; otherwise there can not be.

The valuable objective examination of skioscopy could not be so well made nor could the results be so accurate, if done when the eye is uninfluenced by a mydriatic. Properly practiced, under favorable conditions, skioscopy, in addition to detecting and measuring myopia and hypermetropia, shows quickly the existence of astigmatism, the kind and the quantity, and approximately the location of the principal meridians. A method capable of doing so much should not be interfered with by an active ciliary muscle and a contracted pupil.

When we come to the method of ophthalmometry we find that an active accommodation neither hinders nor helps. Since the ophthalmometer deals only with the cornea, we know that its findings must be the same both with and without a mydriatic; for a mydriatic can effect no change in either the corneal curvature or the corneal reflection. If no effort on the inside of the eye was ever made for the correction of corneal refractive errors, as is true in the aphakial eye, and all errors of refraction existed in the cornea alone, we would then have, in the ophthalmometer, an instrument infallible in its findings; and the mydriatic could be sent into *innocuous desuetude*. Although ciliary action prevents our relying implicitly on the ophthalmometer, it is, nevertheless, a great aid in refractive work. Those who bought this instrument and then consigned it to the attic, if they will only bring it down again and cultivate its acquaintance a little more closely, will find in it a worthy friend. Those whose enthusiasm has led them to trust this instrument implicitly will, on more careful study, find themselves victims of

misplaced confidence, for the reasons already given in this paper. The great sin for which the ophthalmometer will have to account is that its introduction led to a vigorous renewal of the effort to discard the mydriatic in the work of refraction. If the mydriatic is an aid in objective examinations, and ought not to be dispensed with, it is still more essential when the subjective methods are to be resorted to, as they must be, if we aim at accuracy in our work.

In our subjective tests there are causes for error, other than activity of the accommodative muscles, but unfortunately none of them are so easily removed as the latter. For the stupidity of the patient under examination there is no perfect remedy; for the carelessness and haste of the operator there is a cure in the combination of knowledge of the conditions under study and a determination to do the best possible under the circumstances. When we resort to the use of the lenses of the test case our aim is to prove the "findings" of our objective tests. If the fixed habit of strain is not suspended by a mydriatic, though we labor long and earnestly, we can never be certain that what we have done is absolutely correct. No one has ever yet learned the art of coaxing the ciliary muscle into a state of rest. When capable of acting it is always trying to correct the error which your lenses are searching out. This subjective test, when unopposed by ciliary power, is soon satisfactorily ended. If the need of a sphero-cylinder has been determined, and yet there is a "modicum of doubt" as to whether the spherical part should be diminished and the cylindrical increased in strength, or vice versa, the confirmatory agency is the Jackson sphero-cylinder, the use of which can be depended on only when there is suspension of the accommodation. If a perfect knowledge of the full error of refraction in every case is necessary, and this knowledge can be attained only by the suspension of the accommodation, then the reasons against the use of the mydriatic can be easily disposed of.

As to the interference with the business of the patient, superinduced by the mydriatic: He comes to the oculist because of the fact that his eye strain interferes with his business in one way or another. Relief is what he needs, and what he should have, relief in the fullest sense of the word, not present relief only, but relief for the future as well. When told that his trouble is due to eye strain he naturally infers that if the cause of that strain is removed freedom from trouble will follow. He comes, possibly, from a great distance, and, though his business may need him at home, he is off seeking comfort, worth more to him than gold. He is a willing subject, and complains at nothing that is needful to be done. He is a young man—old men may suffer with eye symptoms brought on by strain of the extrinsic muscles, but not from ciliary strain—and his accommodation is active. This must be suspended if the full error is to be known. If he is left to choose, after a fair statement of his case has been made, he will agree to the loss of time that must follow the use of the mydriatic, for he wants the work done correctly. Methods and means that are correct for patients from a distance are correct for home people. As to the amount of interference with business, the difference is decidedly in the favor of the home man. Besides, the business man being a sensible man, will not complain at loss of time necessary in order that relief may come, for he remembers how his troubles have, at times, incapacitated him for effective work. There are few whose work in bank, store, or elsewhere can not be done for a reasonable time by a substitute. What is true of the man of business is true of all patients, lawyers, doctors, school-teachers, artists, sewing girls, etc. But the necessary loss of time from the proper use of a reliable mydriatic need not exceed twenty-four to forty-eight hours. If it were necessary, the patient might be sent at once from the doctor's office to the countingroom, or wherever his duties might call him. Of course, near seeing so quickly done would have to be effected by means of a temporary pair of lenses.

The mydriatic whose power is effective and yet, as compared with atropine,

evanescent, is the one that should be chosen. There are few ciliary muscles that will not respond to a solution of hydrobromate of homatropine of the strength of one-third grain to 20 drops of water, 10 drops of which, drop by drop every five minutes, should be put in each eye. In ten minutes after the last instillation the study of the refraction can be confidently commenced. The work completed by both subjective and objective tests, within an hour and a half all told, a few drops of a one-five hundredths solution of eserine may be used, the same to be repeated the next morning early. The patient may then be sent about his business. By the next morning the effect of the mydriatic is entirely gone. As to the general inconvenience to the patient, this can be readily borne or modified by smoked glasses, etc. Systematic effects are rare, and can be combated by appropriate remedies, brandy and morphine. As to loss of time to the operator, this is a myth. While the muscle test and the correction of the refractive errors must be done by the operator, he can safely commit the use of the mydriatic to the office girl, whose time is not so valuable as his own. This method, too, is restful both to the doctor and the patient; for the muscle tests should always be made when the eyes are uninfluenced by a mydriatic. After the eyes are brought under the influence of the mydriatic the subjective and objective examinations of the focal errors are soon over, and the patient does not have to be reexamined on the next day, nor at any other time, as a rule.

As to the objection that the mydriatic may increase tension to the point of exciting an attack of glaucoma: this objection can weigh but little when we consider that this danger exists only in persons beyond middle life; and that in these patients the ciliary muscle has lost more or less of its power, and a weak mydriatic serves to completely suspend what remains. In these cases, especially if the patients are beyond 55 years, the prime object is not to act on the ciliary muscle, but to dilate the pupil, in order that a thorough examination of the fundus may be made for the detection of central choroiditis so common in old people; also that the periphery of the lens may be examined for beginning opacities. When these conditions are detected early, as is well known, proper therapeutic means may check their progress, and make it possible for the patient to have comfortable vision during the remainder of life. Through the small pupil of the old these changes could not be readily detected. After the proper glasses have been determined and the fundus and lens have been thoroughly investigated the myotic should never be omitted if the patient is beyond middle life.

While advocating the complete suspension of the accommodation, that full knowledge of the refractive errors may be attained and made a matter of record, I would not be understood as advocating that the myopic and hypermetropic refraction should always be fully corrected in every patient at the beginning. On the contrary, in the light of our present knowledge, such practice should be avoided, not only for the comfort of the patient, but also for the credit of the practitioner. In the present state of our knowledge there is not a single reason for not correcting fully all the astigmatism that may be found in any case; but not so with the hypermetropia and the myopia that may complicate it. The relationship between the external and internal recti should always be known before prescribing convex or concave spherical lenses. This should be determined when the eyes are uninfluenced by a mydriatic.\* The superior and inferior recti and the obliques may not be consulted when glasses are to be prescribed.

In prescribing spherical lenses for esophoric cases there is an absolute need for the mydriatic in its full power, regardless of whether the refraction is hypermetropic or myopic. If hypermetropia is associated with esophoria, the accommodation should be fully suspended, not only that the whole of the refractive error may

---

\* See Ophthalmic Record No. 11, vol. 2.

be known, but that it also may be corrected fully. Such glasses will cure a part (the pseudo-esophoria) of the esophoric condition, if not all. As I have been able to show in a former study, the esophoria associated with uncorrected hypermetropia is not all due to the intrinsic power of the internal recti. Further observation leads me to suggest that, for every diopter of hypermetropia in each eye, there is a half degree of pseudo-esophoria (1 D. of H. in each eye would give 1 degree). What esophoria is left after giving a full correction of the hypermetropia must be cured by operation or exercise, or by both. A full correction of the hypermetropia should always be given in cases of internal squint.

\* When esophoria is associated with myopia the mydriatic should be used to full suspension of accommodation, that the very great error of giving an overcorrection of the myopia may be avoided. The exact correction should be known and recorded. The same may be prescribed for distant seeing without risk of adding a pseudo-esophoria to the true muscle error; but the fully correcting concave lenses should not be prescribed for near use, for the reason that the muscle error would be thereby increased. When the esophoria has been cured the full myopic correction should be worn for all distances.

In prescribing spherical lenses for exophoric cases, there is an absolute need for the mydriatic in its full power, whether the refraction is hypermetropic or myopic; for it is in these cases that the true error of refraction is most likely to be concealed, because of the spasm of accommodation caused by the exophoria. Exophoria often causes emmetropic eyes to appear to be myopic. It renders latent the greater part of a hypermetropic error, and adds a pseudo-myopia to the real myopia. The mydriatic alone is able to show the refraction of exophoric eyes in its true state. Without it, concave lenses will be selected by emmetropic eyes, not infrequently, under these conditions, hypermetropes choose concave lenses. While an overcorrection of myopia should never be given, the full correction of a myopia associated with exophoria should always be prescribed, and the patient should be directed to wear these lenses for all purposes of vision. While the hypermetropia associated with exophoria should always be known and recorded, the full correction should not be given, often no correction, until the muscle error has been cured by means at our command.

Orthophoria is rare, but when it exists a full correction of any and all refractive errors should be given. That an overcorrection of myopia and an undercorrection of hypermetropia may be avoided in these cases, the full suspension of accommodation is essential.

Instead of using the mydriatic once in 46 cases, have we not strong scientific reasons for using it 46 times in 46 cases? The human eye remains a human eye under the influence of the mydriatic, except as to its focal adjustment. In this respect it is no more than a machine, and is susceptible of perfect measurement by means of our several objective and subjective methods. In no other way can accuracy be attained. The unscientific cry of honest but misguided oculists against the use of the mydriatic is to the ear of the quack spectacle vender a sweet sound which he attunes to his own profit, and to the detriment of the unsuspecting public. May it soon be heard no more in the land.

## ASTIGMATISM FOLLOWING CATARACT EXTRACTION AND OTHER SECTIONS OF THE CORNEA.

By EDWARD JACKSON, A. M., M. D.,

*Professor of Diseases of the Eye in the Philadelphia Polyclinic; Surgeon to Wills Eye Hospital.*

In his work on the anomalies of accommodation and refraction of the eye, Donders stated, "To the very ordinary causes of altered and consequently irregular arching of the cornea belongs the extraction of cataract. Especially when prolapsus iridis or threatening prolapsus has existed, whereby the pupil has lost its central position, or where, with forward projection of the flap, the wound surfaces do not perfectly correspond, we seldom obtain a completely normal arching of the cornea. If the deviation is slight, the power of vision may still be quite sufficient; but on accurate investigation it now appears that the acuteness is defective, and the astigmatism is in this instance also partly capable of correction by giving an oblique position to the convex glass, or by combination with a cylindrical one." Since the publication of Donders's work almost every text-book upon the refraction or diseases of the eye has contained an allusion to the subject, but these allusions little more than call attention to the existence of such astigmatism. A few papers upon the subject have appeared from time to time, but, so far as I know, only one in the English language—namely, that by Dr. Swan M. Burnett, in the *American Journal of Ophthalmology* for 1889, page 361. In view of this, it seems worth while to here record some observations as to the clinical history of such astigmatism.

*Frequency.*—It appears to occur almost universally after cataract extraction. In a few of my earlier cases my notes do not show that it was detected. But in none of these cases was full vision, or nearly full, vision obtained; and they were not subjected to careful study with the ophthalmometer or the shadow test, so that their negative evidence is not conclusive. In 48 cases that have been carefully studied the amounts of astigmatism present were: Less than 1 D. in 5 cases, 1 to 1.75 D. in 6 cases, 2 to 2.75 D. in 18 cases, 3 to 3.75 D. in 10 cases, 4 to 4.75 D. in 4 cases, 5 D. in 2 cases; 6, 7, and 8 D. each in 1 case. From these statistics I am inclined to think that those who have found it frequently absent have failed to note it, as I did, in the cases previously mentioned, because it was not looked for carefully enough. It would appear from these figures not only that it is present in an amount that can be detected, but also that in a great majority of cases it is present to such a degree that its correction is a matter of considerable importance.

*Direction of the principal meridians.*—All writers who have alluded to this subject have noted, what is shown in my own cases, that, contrary to the rule, the principal meridian of greatest hyperopia was at or near the vertical, the section being made either upward or downward. This has been so generally observed that we may take it as settled that the meridian of greatest hyperopia is usually or always perpendicular to the center of the corneal incision. In many of my own cases the slight difference in height between the puncture and counter puncture clearly influenced the inclination of the principal meridians. The greatest departure from such a position of the principal meridians was in the cases presenting low degrees of astigmatism. In one case of astigmatism, 0.5 D., the flattest meridian was found  $55^\circ$  from the vertical. As to the explanations of the direction of the astigmatism, as well as of its occurrence, more will be said later.

*Seat of astigmatism.*—After cataract extraction this can only be in the surface of the cornea, and in cases of iridectomy, also, the ophthalmometer has invariably revealed that the asymmetry had a similar location.

*Time of appearance and clinical history.*—The first application of accurate methods for the measurement of refraction subsequent to the operation has invariably revealed the astigmatism present, and in the highest degree exhibited at

any time in that particular case. Inspection of the cornea, with or without the use of the Placido disk, from the date of operation shows that after the effects of cocaine have passed away and the humors have replaced the extracted lens the form of the cornea remains normal, although subject to changes by changing pressure from the lids, until the interior chamber is reestablished. Then in the course of two or three days, or sometimes in a few hours, the corneal asymmetry becomes evident and quickly reaches its maximum. From this time on the tendency is for the astigmatism to diminish, until at length a permanent condition is reached. This diminution, however, is not always regular or constant, as was well illustrated in many of the cases. For example :

Mrs. J. M., aged 54 : iridectomy for subacute glaucoma, corneal section upward, well back in the sclero-corneal junction, involving one-fifth of its circumference. The eye was operated on May 14, 1883. It had previously been carefully examined and found hyperopic 2 D. and free from astigmatism. The astigmatism was evident shortly after the operation. In five weeks it had markedly diminished, and +4 D. cyl. axis  $25^\circ$ , gave vision equal four-sixths. At nine weeks there had been no change whatever in the refraction, and the above cylinder was ordered for distance, with +3 sph. added for reading. Sixteen days later the patient wrote me complaining that the glasses had begun to hurt her eyes, and was instructed to discontinue their use. At fourteen weeks the refraction was again carefully tested and found to require for its correction +2 sph.  $\ominus$  +2.50 cyl. axis  $20^\circ$ , giving the same vision. At eighteen weeks the same correction was required, but fearing further diminution of the astigmatism she was ordered for distance +2.25 sph.  $\ominus$  +2. cyl. axis  $20^\circ$ . Four years later she required +2.75 sph.  $\ominus$  +2.50 cyl. axis  $13^\circ$ , and with it obtained a vision of four-fourths, partly. There was no further change in the refraction when last seen, more than eight years after the operation.

In watching cases from week to week with the ophthalmometer, it has repeatedly happened that for some weeks the change in the astigmatism would be but slight, and then there would suddenly appear a rapid change to what proved to be the permanent condition. On the other hand, there will in some cases be a steady diminution of the astigmatism from the time it is first measurable until the permanent condition is reached. Thus:

R. C., aged 63, after simple extraction, upward section in the margin of the cornea had at 14 days, astigmatism 15 D. convex cyl., axis  $155^\circ$ ; at 21 days, 13.5 cyl.; at 40 days, 11 cyl.; at 54 days, 7.5 cyl., now axis  $157^\circ$ ; at 61 days, 7.5 cyl.; at 75 days, 5.75 cyl.; at 78 days, 5 cyl., axis now  $158^\circ$ ; at 90 days, 4 cyl., axis  $158^\circ$ , giving a vision of four-fifths, mostly.

In nearly half of my cases capsulotomy was performed while the patient was under observation. No effect from it upon the astigmatism present could be noticed.

*Final amount.*—The amount of astigmatism remaining when its condition had become permanent is indicated in the table given in connection with its frequency. It should, however, be noted that all cases in which the astigmatism is given as over 4 D. were cases that have not been seen more than five months after the date of operation, and of the cases showing 4 D. but two were seen more than six months after the operation; so that it is uncertain whether in any case more than this amount of astigmatism has remained permanently. Although some of these cases are known to be within reach, and all were directed to report if their glasses became unsatisfactory, the one in which the astigmatism was 8 D. was seen only one month after operation. It is certain that in the large majority of cases the amount of astigmatism diminishes to less than 3 D. before it becomes fixed. And in a given case where it was necessary to adjust glasses within the period of probable change of astigmatism it would be safer to prescribe for this average amount than to take the measurement of the eye at the time if it indicated a higher amount, even though this might have been almost or quite constant for days or weeks.

*When it ceases to change.*—The period during which the astigmatism continues to diminish varies widely. In two eyes it decreased from 4 D. to 2.25 D. after a

period of six months had elapsed. In another case it had fallen to 2.25 D. by the twenty-second day, and no further change occurred, although the eye was seen for more than a year afterwards. In another case it diminished to 1.25 D. by the twenty-fifth day, and remained without the slightest change five years later. In still another, it fell to 1 D. by the twenty-third day. In about 60 per cent of the cases the change continued between two and three months, with perhaps a very slight diminution after this. In 15 per cent permanence was reached in the second month; in 20 per cent change continued after three months. Where the amount remains high at the end of this period, even though it has been for a considerable time stationary, there is strong probability that it will further diminish later. All of the cases long under observation, two of them for ten years, seem to show that after a certain period, limited apparently to the first year, or possibly a little longer, the amount of astigmatism becomes quite fixed and is as little liable to change as in cases of moderate astigmatism not due to operation.

*Influence of complications.*—The occurrence of prolapse of the iris or of incarceration, or even of close adhesion of the iris to the corneal stump, notably influences for a time the amount and delays the diminution of astigmatism, but these conditions appear to produce but little effect upon the final amount and permanence. The influence of prolapse in this direction, unless it be so extensive as to cause great displacement of the corneal flap, is not greater than the influence of incarceration or of adhesion of the iris to the cornea. In either case the influence appears to be proportioned to the extent to which the corneal wound is involved. Thus, a large incarceration is worse than a small prolapse. In the series of cases upon which this paper is based, there occurred two of extensive prolapse of the iris allowed to shrink without excision or other operative interference.

W. J., aged 70, by a sudden movement of the eye during the corneal section, caused a doubling of the incision that left about one-third of the margin of the flap hanging as a shaving of corneal tissue, almost completely severed from its connections. This underwent partial absorption, delaying the healing of the wound, and the restlessness which had caused the original accident secured an extensive prolapse of the iris. On the twenty-sixth day he still had 10 D. of astigmatism, which, however, had diminished to 3.50 D. by the seventy-seventh day, and after that underwent no change.

J. W., aged 42, had a bit of steel lodged in the lens four months previously. The lens was much swollen, and in order to make sure of the removal of the foreign body, a long incision well back in the sclero-corneal margin was employed. Prolapse of the iris occurred and extended until it occupied the whole length of the wound. It reached its maximum in a few days, and then remained without notable change in bulk for thirty days, after which it flattened rapidly, and by the forty-fifth day had gone down entirely to the level of the cornea. On the fifty-first day the astigmatism was 20 D. ;\* on the fifty-eighth day 11 D., at sixty-five days 9 D., and only after five months has it reached 5 D.

In contrast to this is the course of the astigmatism in the following case :

Mrs. J. G. B., aged 64 ; simple extraction, normal healing ; on the twenty-fifth day, astigmatism 26 D. ; on the twenty-eighth day it had fallen to 23 D., and in two months and a half to 0.75 D.

*Nature of the change in the cornea.*—The readings of the ophthalmometer show, first, that the corneal curvature is actually diminished in the meridian of least refraction, usually vertical, or nearly so, and that this meridian is flattest at the first examination and becomes more convex as the astigmatism diminishes; second, that the meridian of greater curvature, usually horizontal, or approxi-

\*The numbers of diopters in this and the following case are, what was indicated by the Javal ophthalmometer, considerably higher than the convex cylinder accepted. Thus when the ophthalmometer showed 11 D. the 10 D. cylinder was chosen. When it showed 23 D. the 18 D. gave the best vision. This is partly because of the distance of the cylinder in front of the eye, and partly because the constants taken as the basis of the graduation of the Javal instrument do not hold for the eye rendered aphakic by cataract extraction. (See paper by Dr. Carl Weiland, Archives of Ophthalmology.)

mately so, presents an actual increase over the previous curvature of the cornea, which increase is greatest at the first examination and diminishes with the astigmatism; sometimes, but not always, passing away altogether by the time the condition of permanency is reached. To explain these corneal changes, the pressure of the lids, the displacement of the flap, and the action of the extra-ocular muscles upon the globe have all been invoked, but the astigmatism occurs, typical in form and course, when the flap and stump unite in perfect coäptation; and the pressure of the lids and action of the extra-ocular muscles have not been shown to differ essentially from their pressure and action on the normal globe. It seems to me that the explanation of the phenomena of post-operative astigmatism is to be found in the essential fact of an incision through the resisting coat of the eye, temporarily entirely destroying its resistance along a certain line, and that the necessary effects of such an incision, irrespective of any outside influences, are just such as we have observed in cases in question. With the incision the resistance of the sclero-corneal coat to the intraocular tension along the line of incision drops to zero and remains there until the flap and stump adhere. During this time that the wound remains open the intraocular tension also remains at zero, and no displacement results. When, however, the wound is closed the intraocular tension is immediately renewed and the adhesions uniting the flap and stump become a portion of the sclero-corneal coat, which has to resist this tension. Throughout most of this coat the power of resistance is normal, the adhesions possess comparatively little power of resistance, and the changes in the neighboring margins of the flap and stump incident to the process of repair materially diminish resistance. It follows, therefore, that we have along the line of incision less resistance to the intraocular pressure than at any other portion of the sclero-corneal sac; necessarily the parts where the resistance is less protrude. This protrusion causes great increase of curvature in the direction perpendicular to the incision at the line of incision; and this increase of curvature must necessarily be made up by an equal amount of flattening of the neighboring portions of the cornea and sclera. In the sclera, this flattening being of no practical importance, remains unnoticed. In the cornea it causes the flattening of the vertical meridian. So much for the flattening in the meridian perpendicular to the incision. It is noticed that the change of outline that occurs is dependent on the bulging of the point of least resistance. The maximum of this bulging will be at the center of the corneal incision; that is, the center of the corneal incision is more pushed out from what would be its normal relation to the center of the globe than any other point of the sclero-corneal coat; and the whole area of the central part of the flap shares more or less in this bulging. We have, therefore, the center of the upper part of the flap bulging forward. If other parts of the circumference of the cornea remain fixed, as the whole cornea does outside of the region of incision, and as the angles of the incision do, to a less extent, because of the support they receive from neighboring firm tissue, this bulging at the upper margin of the cornea causes the cornea to assume more or less the form of a vertical ridge, comparatively flat in the direction of its length, but with increased curvature from side to side. And in this increase of curve, to get over the ridge as it were from side to side, we have the cause of increased curvature in the meridian of greatest curvature.

This explanation is put forward not as an hypothesis, but as an application of perfectly understood physical laws to the special case of intraocular tension, resisted by the sclero-corneal coat, weakened along a certain line of incision, and seems to me entirely adequate to the requirements of the phenomena in question, rendering unnecessary any appeal to other special causes to explain post-operative astigmatism. As the resistance along the line of incision increases with the return of the tissues to normal, the tendency of intraocular pressure is to reproduce the

normal spherical curves, or the spherical curves of the normal eye. That it should fail of doing this completely is not to be wondered at when one considers the existence of the permanent scar and the comparative rigidity, on account of the age of the patient, of the tissues in which this process generally occurs. The influence of such complications as prolapse or incarceration of the iris is clearly traceable to the fact that they produce softening in the adjoining margins of the flap and stump, and delay their return to the conditions of normal corneal tissue.

*Choice of operation and after treatment.*—The hope has been expressed that with an increased knowledge on the subject of post-operative astigmatism, we would be able to choose or devise some special form of operation that would reduce it to a minimum or prevent it entirely. But if the cause lies in the essential fact of an incision into the cornea that necessarily lessens its resistance, this hope will have to be abandoned. All we can do in the choice of an operation will be to keep the incision out of the visual zone of the cornea, and to secure prompt and complete healing. The thought will occur that if the bulging could be prevented by the proper outside pressure, the astigmatism would be prevented. But, as I have already urged in a paper before the American Medical Association, in 1891, any such application of pressure is impracticable and the attempt certain to be injurious. Where prolapse or incarceration of the iris has occurred, the removal of the involved iris may hasten the condition of permanence, but will not diminish the ultimate amount of astigmatism sufficiently to justify a resort to it on that account.

*The correction of post-operative astigmatism.*—Many of those who recognize its existence speak of it as unimportant, or to be corrected not by a cylindrical lens, but by the placing obliquely of a spherical lens. The need of the improvement of vision gained by the correction of 1 or 2 or 3 D. of astigmatism is as great for a patient who has undergone cataract extraction or iridectomy, and so speedily acquired the astigmatism, as for a patient in whom the astigmatism is congenital, or of slow development. The imperfect visual acuteness often present in the former class of patients is, I believe, more than balanced by the fact that astigmatism is new to them. Even if its correction will not give as good vision as may be obtained by the correction of some case of congenital astigmatism, the fact that the patient has been accustomed to seeing without astigmatism will cause him to appreciate as highly the relief afforded. In any case of cataract extraction that can be properly classed as successful, it seems to me important to correct the astigmatism.

Now, as to the method of correction. Theoretically, it is true that by looking obliquely through a strong spherical lens regular astigmatism may be corrected, but, as I pointed out in a paper read before the American Medical Association, in 1887, on the effect of obliquity of correcting lenses, such a correction is far less satisfactory and far less beneficial than the correction by the ordinary cylindrical lens. The proper cylindrical effect is only obtained at a certain angle and at an angle where the slightest deviation either way produces a perceptible change in the cylindrical effect, so that the patient who gets his cylindrical effect by looking obliquely through a spherical glass is constantly getting, instead of the proper effect, not enough or a little too much. On the other hand, with the cylindrical lens, and the visual axis perpendicular to the lens, there is a considerable angle to either side of the perpendicular through which the change of cylindrical effect is imperceptible; and on this account, if the lenses are properly mounted, it becomes difficult for the patient to get a cylindrical effect which will be seriously incorrect. One other point. The reason urged for not employing a cylindrical surface upon the cataract glass is that it renders necessary the use of a more convex spherical surface, increasing the weight of the lens and the amount of spherical aberration. The increase of weight in a plano-spherical over a double convex that is absolutely necessary is so slight as to be of no practical importance. The increase that happens in the use of such lenses in practice depends on the inferior selection

and grinding of the lens by the optician. The spherical and chromatic aberration of even a strong cataract glass, especially through the small pupil obtained by simple extraction, are not the most serious defects in a strong lens. The effect of looking obliquely through the lens is of much greater practical importance. And by placing the spherical entirely on one surface, if convex, the surface away from the eye, we secure an approximation to the ideal periscopic lens, one which should have the center of its refractive surface at the center of rotation of the eyeball, and reduce to the minimum the effects of looking obliquely through the refracting surface. Indeed, so important is this matter that where the cylindrical lens was to be employed in connection with the strong spherical, I have used the concave cylindrical with the convex spherical, turning the former toward the eye, the latter from it, and have found such a lens as satisfactory or more satisfactory than those made with both spherical and cylindrical surfaces convex.

The teaching of the non-correction of astigmatism after cataract extraction seems to me utterly opposed to good sense, and practice based upon it is only excusable on the ground of an insurmountable constitutional indisposition to do thorough work.

---

#### A FEW THOUGHTS ABOUT OPHTHALMOMETRY; AS TO WHAT THE JAVAL INSTRUMENT WILL DO, AND WHAT IT WILL NOT DO.

By LOUIS J. LAUTENBACH, A. M., M. D., Ph. D., of Philadelphia,  
*Surgeon to the Pennsylvania Eye and Ear Infirmary, Chief of the Eye Clinic of the German Hospital, etc.*

The value of the ophthalmometer as a factor in the determination of the axis and amount of astigmatism has for the past few years given rise to considerable controversy. According to some it would seem as though the ophthalmometer had supplanted the subjective test, rendering the use of mydriatics unnecessary, and those who used them liable to be considered old fogies, too "sot" in their ways to appreciate the value of the more perfect and scientific method. Others consider it little more than a toy whose popularity will be ephemeral, and content themselves with the assurance that it, like many other medical fads, rests on an insecure foundation and will therefore soon be a thing of the past. Again, there are those who consider the instrument a scientific one, constituted on proper principles, and not a toy; yet know that the scope of its work is limited, and have endeavored to get from it all that is possible, and while acknowledging its great usefulness, realize its limitations.

Those who have used the ophthalmometer, in other words, those who from experience know something of it, naturally belong either to the first or third group. Originally the larger number of them belonged to the first class; but the third or conservative class has been steadily growing, and now contains quite a respectable number of the thinkers, or, in other words, it contains the workers and reasoners, and not the enthusiasts. The main reasons for this difference of opinion consist, firstly, in a faulty construction of the instrument; secondly, to a faulty use of it; and thirdly, a wrong interpretation as to what can be accomplished with it.

Glancing for a few moments at the different ophthalmometers, we have to consider, first, the original instrument constructed by Helmholtz in 1853. This instrument is really perfect in construction, giving us most accurately the radius of curvature at any part of the cornea desired. Its results are accurate, but its use entails the expenditure of a large amount of time. To thoroughly measure the cornea at any point necessitates at least sixteen separate readings. It has been used by Knapp, of New York, and Strawbridge, Wieland, and others, of Philadel-

phia. All testify to its accuracy and perfectness, but consider it more valuable in the laboratory than the office. The ophthalmometer of Le Roy and Dubois has the disadvantage of being poorly constructed, the hinge and other joints being loose; in fact, nearly all the fittings are inaccurate. There is no means of steadying the head so that the eye may be fixed while being measured; the scale is inaccurate; the bar on which the mirrors or reflectors ride is straight, whereas it should be an arc of a circle with a radius equal to the distance of the scale from the eye being examined. It has no means of artificial illumination, while requiring for its proper use a very strong light. Some pretend that by its use the refraction of the eyeball can be determined. The claim is, however, too absurd for discussion, as it must be evident that it is a physical impossibility to determine this objectively. The Javal-Schiotz ophthalmometer of 1889, if mechanically well constructed, is a good instrument. Its most frequent defects are a displacement or a malposition of the Wollaston bi-refrangent prism, a displacement of the arc upon which the scale is constructed and the mirrors move, the want of a means of keeping the patient's head fixed while under examination, and an insufficient illumination. In the Javal instrument (model of 1889), of French construction, the base is too light, it does not keep the telescope and head rest in a fixed relation to each other, and in the general workmanship it is markedly inferior to that of American construction. A malposition or displacement of the Wollaston prism is frequent. Instead of the primary image revolving about its center with the revolution of the telescope, it has, in addition, another motion about an imaginary center, the secondary image in either case moving about the primary one. This double motion of the primary image is due to a faulty position of the prism, and before using such an instrument it should be carefully overhauled, as all results obtained under these conditions are absolutely worthless. If the arc be not in proper position, if it is not at all points exactly the same distance from the eye, again are the results valueless. The screws by which the arc is fastened to the barrel of the instrument must be very carefully adjusted. In order to test the arc a lens with a refractive power of its anterior surface of about 32 diopters should be placed at the rest of the instrument. If, as the telescope is revolved, there be the slightest break in the continuity of the black lines of the *mires*, it indicates that the arc is still improperly adjusted.

With a properly constructed instrument, a good illumination (four incandescent lights of 16 candle-power each being undoubtedly best), the apparatus firmly secured to a good stout table, and the patient's head firmly fixed (strapped in the head rest), the results will be trustworthy and accurate. It is for us to interpret the results.

Here let us pause and inquire as to what has been expected of the instrument, and how far our anticipations have been realized. There are those who have assured me that it would measure the refraction in any meridian. It is with this idea in view that the scale of the Le Roy-Dubois instrument is constructed. Physically, as before mentioned, this is an impossibility and can not be accomplished. Others consider that it will invariably give both the axis and entire amount of astigmatism of the eye. This it will do only in such cases where the astigmatism is confined to the anterior surface of the cornea; but the astigmatism may not be confined to the cornea, and therefore lenticular astigmatism must be considered, as must also the fact that the posterior surface of the cornea may not be parallel with the anterior; if this be not so, it will influence the astigmatic refraction. In other words, ophthalmometers deal with the cornea only, and are therefore, strictly speaking, keratometers and any knowledge of other parts of the eyeball that they may reveal to us is obtained by a comparison of our other studies with those of the keratometer. In fact, all we obtain is a knowledge of the anterior surface of the cornea, its radii of refraction, its irregularities, and some idea of the transparency and nutrition of its superficial layers. When once this fact

is thoroughly realized there will be fewer disappointments, as well as fewer enthusiastic outbursts than have up to this time characterized the progress of these studies. By means of the keratometer we can measure the corneal area, its curvature at any or all parts, and learn the angle of the axes of the principal meridians at the part under examination, as well as the difference between the radii of curvature at these or any intermediate points, and can thus determine in diopters, the difference in corneal refraction at these points. In addition to this, the instrument has in my hands proven valuable in determining problems as to the nutrition of the cornea, and as to increase or decrease of the intraocular pressure.

My first keratometric work was done with a Helmholtz instrument, but I am now using the Javal instrument entirely, and with it have examined over 1,800 eyes of over 900 patients. In all cases of refractive errors or diseases of the eyeball or its appendages (with the exception of a few cases of acute inflammation of the iris, cornea, and conjunctiva), in addition to the routine examination, a keratometric examination is invariably made. Of these over 1,400 eyes have been thoroughly examined and tested while under the influence of a mydriatic, either atropine or homatropine. As a result of these examinations I have found that the axis of astigmatism, as determined by the keratometer, corresponded to the axis as determined by the mydriatic in 88 per cent of the cases, while the degree corresponded (after making the correction of 0.37 diopters, subtracting it when the astigmatism is with the rule and adding when against the rule) in 45 per cent.

It is an admitted fact that the astigmatism of a ball is not always confined to the cornea; that not infrequently it is lenticular. Of this we have two varieties, the static and the dynamic. In the dynamic variety, supposed by some to be a compensatory effort to overcome the effects of the corneal astigmatism, usually all that is necessary is to carefully correct the corneal astigmatism, the dynamic lenticular astigmatism then disappearing. In the static variety, the ophthalmometer can not give us the total astigmatism. In these cases we must proceed to the estimation and correction of the lenticular astigmatism as well. It is these cases that in the whole range of refraction work gives us the least satisfactory results. In the examination of corneæ which have been subjected to weakening of structure in consequence either of local inflammations or systemic disorders; cases where the results obtained by glasses while under mydriatic influence are either indifferent or nil, because of irregularities in curvature or in the transparency of the corneal layers; we can often get very good results through the aid of the keratometer. By instilling a few drops of castor oil on such corneæ we are often enabled to get very clear images, and can thus determine the axes of the principal meridians and the difference in diopters between their refractive powers.

The approach, advance, and subsidence of glaucoma has been made more noticeable and marked by the changes in the axis and curvature of the cornea and changes in the brilliancy of the keratometric images than by any other method of examination.

In developing myopia it will soon show the suspicious nature of the case, and in progressive malignant myopia the changes are frequent and marked. I have often noticed that irritable retinas are associated with corneæ whose axes and curvature vary, and now I always seek for the latter whenever I find the former. In corneal malnutrition dependent upon syphilitic disease the changing of the axes and curvatures, with a loss in the brilliancy of the reflex, precedes an inflammatory attack, and if this condition be appreciated, serious results will often be avoided. In refracting cases of aphakial eyes, and in refracting shortly after injuries of the cornea, and after operations involving the cornea, its value must be evident to all, giving us results which often we could not obtain without incurring possible danger from irritation and subsequent inflammatory action. Some of the intricate problems regarding the construction of the eye, its depth

and diameters, its lens astigmatism and refraction, can be determined by means of calculations from the data as furnished by this instrument, as compared with those as furnished by the subjective examination under full mydriasis.

Now, briefly outlining, we find that the ophthalmometer will not give us the refraction, nor will it give us the total astigmatism except when this is confined to the cornea, or any knowledge as to whether there is or is not lenticular astigmatism. It will give us the axis and degree of astigmatism when this is corneal. Practically we find that it gives us the axis in 88 per cent and the amount of astigmatism in 45 per cent. It reveals to us a knowledge of diseased conditions of the eyeball when the disease is of such a nature as to interfere with the corneal nutrition or to increase or decrease the ocular tension. It will, in connection with other methods, allow us to calculate the lenticular refraction and astigmatism as well as the depth of the eyeball, and thus puts within our grasp a new method of more thoroughly studying its functions and anatomy.

---

#### DISCUSSION.

Dr. Risley said: I congratulate myself on the fact that the task before me is a pleasant one, since I am in practical agreement with the views expressed in the several valuable papers presented. I am much interested in Dr. Belt's researches regarding the eyes of white and black school children. He had kindly referred to the Philadelphia school examinations. In that work the main endeavor, however, was to show that the universally recognized increase of myopia during the school life was due in large measure to existing astigmatism, which seemed to be confirmed by the fact that in astigmatic eyes, it was shown, were discovered the commencement of those pathological states of the choroid which, in their more advanced states, were characteristic of the myopic eye, while in emmetropia or simple perimetropia or myopia, not only were these changes absent, but the eyes were comparatively free from asthenopia. In the management of refractive errors I feel it important, first of all, that emmetropia should be accepted as the model eye and all departures from this accepted as defects, and when pressure in asthenopic eyes should be corrected by glasses. As to the methods to be pursued in the management of these cases, it should differ widely in different cases when the choroid and retina are practically healthy; in many instances approximate corrections will secure the comfortable use of the eyes, and may be made without the use of a mydriatic, or with the careful use of homatropine; but in cases of retino-choroidal irritation, with their woolly or "ripe-peach" eye grounds, time is an important element in their treatment; hence any endeavor at rapid correction was liable to prove futile. In late years a very large percentage of the cases I have seen had bad eye grounds and needed the mydriatic, not only to paralyze the accommodation, but as a therapeutic agent. In such cases the drug should be employed until the turgid state of the intraocular tunics subsided, when the correcting glasses would be chosen with but little difficulty. It required time to accomplish this, and while the same end could be reached with the employment of homatropine it should be applied more frequently and must be used longer than the stronger mydriatics. For this end he preferred hyoscyamine, and although the resulting effort was more enduring than that of homatropine, the total time of detention from work was no longer, and on the whole more satisfactory and less annoying to the patient than the prolonged and frequent instillation of homatropine. Regarding the use of the alkaloid disks, after a persistent trial he had returned to neutral solutions in water. When combined with cocaine they caused increased lachrymation and the tears either diluted the alkaloid or washed it away. Then, too, the cocaine lessens the intraocular tension and often disturbs

the corneal epithelium. Solutions in oleaginous substances, he quite agreed with Dr. Wood, were inadmissible for the reasons stated, as he had ascertained by trial in 1875. No mention had been made of the later chemical results in the manufacture of the mydriatic alkaloids. If the alkaloid is extracted from *atropa belladonna* in the presence of an alkali or of great heat the product is atropine, but if no alkali is employed and only low temperatures used, hyoscyamine is the resulting product, while, on the other hand, in the presence of high temperatures and an alkali, atropine is the product, even from *hyoscyamus nigra*. It was important, therefore, that in dispensing hyoscyamine sulphate that the solution should be neutral and made at low temperatures. Recently, preparations of sulphate of atropine and sulphate of hyoscyamine were given by me to Dr. Marshall, of the University of Pennsylvania, and neither of the drugs showed any paralyzing power, hitherto the only means, except their physiological properties, of differentiating them. It would therefore appear that the products now in the market, certainly those from Merck's laboratory, are both hyoscyamine, and that we get atropine only through the careless manipulation of the druggist. A 1 per cent solution of duboisine to hyoscyamine was too strong to use in the manner suggested by Dr. Wood and would in many cases give rise to toxic symptoms.

In reply to Dr. Savage's paper I would say that I am in full accord as to the urgent necessity for mydriatic corrections if we are to secure any but the barest approximations to the static refraction of the eye. I can not, however, agree on the statement that old men do not suffer from eye strain. The ciliary muscle is still present and susceptible of contraction however futile its efforts may be over the now flat and inelastic lens. This is frequently demonstrated in the irritable eyes and headache of old people, reading or working with an improperly adjusted glass. In these conditions a mydriatic often gives as great relief from these asthenopic symptoms as in younger people. The pin-point pupils of people at 50 years reading without glasses, or with too weak glasses, demonstrates still further the existence of eye strain, and hence the frequent need of a cycloplegic after 40 years of age. I have no fear of the glaucoma ghost which has been held up before us from the use of mydriatics in middle life. I have used them in thousands of people beyond the mydriatic dead line, and no harm has ever followed. It would, of course, be folly to use them in cases where glaucoma was imminent, or in suspicious cases. These should be excluded. I do not believe the spasm of accommodation is by any means confined to cases of exophoria, as I have frequently seen marked spasm which has disappeared under prolonged use of mydriatic and no exophoria was demonstrable. My own experience is in accord with the teachings of Dr. Jackson's paper. The astigmatism following operations which opened the anterior chamber, I believe, occurred quite uniformly. I have recently performed extractions in two cases in which the existence of astigmatism has been demonstrated before extraction, the axes of the correction cylinder being required at 90°. After extraction a much higher grade of astigmatism was present with the axis of the correcting cylinder at right angles to its former position. My experience also showed a more or less rapid diminution of the astigmatism found to exist two weeks after extraction. The permanent degree probably averaged about 1.25 D. and the axis of the cylinder was ordinarily required approximately parallel to the line of the cicatrix.

I was much pleased with the admirable statement by Dr. Lautenbach of the proper values of the ophthalmometer. I use it quite constantly as an addition method, but I can not trust it sufficiently to justify me in ordering cylinders by its readings since, in a careful analysis of 200 eyes, subsequently corrected under mydriatics by subjective examinations, 25 per cent showed important discrepancies.

Dr. Burnett said: I was interested in the statement of Dr. Belt that he had found approximately the same number of squints in the white and colored children.

My own experience in clinical and private practice has been that squint, especially of the concomitant form, is very rare in the negro. I coincide fully with Dr. Jackson, since the results as reported by him as to astigmatism following cataract extraction are in accordance with my own, published three or four years ago. He did not think that on the average the eye regained its final shape after an extraction, on an average, under two months. I think Dr. Lautenbach's estimate of the ophthalmometer just. It would give us only the astigmatism of the cornea, but is, on the whole, one of the most valuable instruments we have, and if once used understandingly would never be given up. It did not give us the lenticular astigmatism directly, though it had done more than any other instrument to demonstrate its existence. (He gave the history of a case examined that morning which showed that neither the ophthalmometer nor the shadow test could be relied upon implicitly). In this case the shadow test showed those internal shadows of which I have spoken at a late meeting of the Ophthalmological Society, and whose presence indicates, in my mind, some irregularity in the refraction of the lens, and made the findings of the shadow test unreliable. I am of the opinion that in some particulars the old instrument of Javal is the better, particularly as to its prisms.

Dr. Gould thought that in the great majority of cases of eye strain without complicating disease, the long-continued use of a mydriatic as a therapeutic agent was an unnecessary tax on the patient. The glasses are the therapeutic agent. Physiologic action, not paralysis, is true therapeutics. He finds that homatropine and cocaine in pure solutions, properly exhibited, give perfect mydriasis.

Dr. Snellen said: Dr. Jackson stated this morning that operations for cataract or iridectomies are always followed by astigmatism. I quite agree with him that this is due to the loosening of the tissues and the bulging of the sclerotic. The more the wound is in the sclerotic the more astigmatism one gets. After a paracentesis of the cornea no astigmatism occurs. Up to now no one knows to what the good effect of iridectomy is due. My father, Professor Snellen, started the idea that it was due to this astigmatism, or rather to the cause of it; the bulging of the sclerotic which opens the perilenticular space. Priestly Smith, of Birmingham, sought the cause of glaucoma in closing of this space.

Dr. Hansell said: My experience in refraction of aphakial eyes agrees in the great majority of cases with the observations made by Dr. Jackson, that astigmatism diminishes during the few months following the cataract extraction. I have had, however, a case which has proven an exception. Four weeks after operation I prescribed  $+12 \text{ C} +4 \text{ cyl. ax. } 180^\circ$ . Four months later I reexamined and discovered that the astigmatism had remained unchanged but that the Hypermetropia had increased to  $16^\circ$ .

Dr. Baker, of Cleveland, Ohio, said: I am pleased with the conservative character of the papers read; and yet I suppose that every ophthalmic surgeon is at liberty to use his own judgment and experience as to the choice of mydriatic, and the method of examination, either objective or subjective. When a patient presents himself at my office complaining of eye trouble, immediately after making a few general inquiries I take him into the dark room and examine him with the retinoscope. This examination should be made in a large dark room and without a mydriatic. Many of the difficulties complained of by Dr. Burnett in his case this morning will not be met with in the undilated pupil. The inability to discover the point of reversal in retinoscopy with the dilated pupil, I think, is often due to an irregular refraction at the margin of the lens. I then test the patient with the Snellen test type and trial lenses and if I get the same result as in the retinoscopic examination I feel perfectly justified in prescribing lenses without resorting to mydriatics, and I think these include fully one-half of my refractive cases, not including presbyopic ones. My cases do not all come to me because of

pain and eye strain; in fact, a large percentage come for imperfect vision, and if I can improve the vision without using mydriatics I see no occasion to subject the patient to the inconvenience of their use. I frequently make an exception in cases of low degrees of myopia. An overcorrection in these cases would prove disastrous. There is no danger of overcorrecting hypermetropia, and an undercorrection is not objectionable; and the amount of astigmatism can be accurately measured by retinoscopy. In low degrees of myopia I frequently use homatropine. I thoroughly believe with Dr. Risley in the therapeutic value of atropine in cases of eye strain, even though no pathological changes can be discovered in the fundus. These overworked eyes need rest. Frequently it is impossible to send these cases to the mountains or seashore, and the best substitute I can subscribe is absolute rest for two or three weeks under atropine, and I frequently prescribe it for this purpose. Parents often will not remove their children from school, and I take this method of enforcing my demands. I find the presoptometer of the late Dr. Culbertson of much use to me in cases of amblyopia in young children who can not read and in ignorant, dull people as a substitute for the test type.

Dr. Kollock, of Charleston, S. C., said: My experience with the negro shows a much greater percentage of corneal disease than has been incidentally mentioned by Dr. Belt. In my practice among the negroes more than 37 per cent of all diseases were corneal. With regard to strabismus in the negro I agree with Dr. Burnett that it is never seen in the pure-blooded negro except in cases of corneal defects, paralysis of the orbital muscles, cataract, or disease. In the mulatto it is not uncommon, though not as frequent as in the white. I think in testing these troubles in the negro care should be taken to state whether they were mulattoes or pure negroes. The mulatto has all the refractive troubles seen in the white, though not as common; the pure-blooded negro has little refractive trouble, slight hyperopia, and rarely myopia. With reference to Dr. Jackson's paper, I have seen an interesting case of corneal astigmatism following a corneal section for glaucoma. This section was made with a lance knife. The anterior chamber filled with blood, and tension instead of being reduced became of strong hardness. This continued for two days and vision was nil. Weak solutions of eserine failed to reduce the tension and the 4-grain solution was used with the result of rapidly reducing tension and restoring vision. This vision was 15, and no glass or combination of glasses would improve, but the stenopœic hole gave  $\frac{15}{30}$ . About a month later vision was brought up to this point by a compound lens.

Dr. Tiffany, of Kansas City, said: Dr. Belt in his report of the examination of school children, white and colored, says that he notices that some of the hyperopes after a few years increased in their hyperopia. We can readily understand how an eye can appear or even become emmetropic. My examinations of school children and students show many pupils of 10 to 12 years with a fraction of 1 to 2 dioptries become at 18 or 20 absolutely emmetropic or even myopic, but never more hypermetropic. When we speak of hypermetropia we mean the static refraction and not the dynamic. The dynamic conceals the hypermetropia to a great degree. I remember one patient, a young lady of 20, a teacher, who came to my office with  $\frac{20}{20}$ , but, with the dynamic set aside, her vision was  $\frac{5}{20}$  requiring a +6 D. to gain  $\frac{20}{20}$ . The fact is that hypermetropia does not increase but myopia does.

Dr. P. D. Keyser, of Philadelphia, said: I regret that I was obliged to leave this morning before hearing all the papers read, my duties requiring my attendance in the section of hygiene for the time, but to the remarks of Dr. Kollock in relation to the negro never having myopia I must say that there must be a difference in the eyes of the black race in the South from those in the North, although our confrères of the South have much greater advantage in seeing more eyes of the negro than in the North, but in my experience of more than twenty years in the Wills Eye Hospital, of Philadelphia, I have found several that we call pure negroes suffering

with well-marked myopia as well as compound myopic astigmatism. One case, near my office, of a very dark coachman of a well-known physician of our city wears 6 spherical, and only last week I fitted a compound myopic astigmatism. Really, in my experience I find as the negroes are being educated to read that their attention is being called to the defect in vision and they seek assistance, and in proportion as these educated persons come to my clinic I find almost an equal defect as in the white. In relation to Dr. Jackson's paper on astigmatism following cataract extraction, I desire to state that v. Graefe in 1883-84 called attention to the defect after his modified linear incision, and I have noticed it in all extractions by any form or place of incision, as well as in iridectomy. I look at it being caused by the swelling and thickening of the cicatricial edges of the corneal incision in the process of healing; always soon after the healing of the wound the irregular curvature of the cornea is much greater than is found after several months. It is very frequent that it is necessary to change the cylinder six, twelve, and twenty-four months after from the change in the cornea caused by the shrinkage of the cicatrix. It is very rare that astigmatism is not found in operations on the cornea which requires correction for good vision. I agree with Dr. Savage in the necessity for complete paralysis of accommodation in many cases of examination and adjustment of glasses; especially is it necessary in small children who have strong muscular power and unable to aid the examiner. Homatropine and such remedies do very well in adults and are mostly sufficient, but are not so in children. With them atropine to complete suspension of accommodation gives the best result in many cases. But judgment is necessary in making a full correction. I find many cases in which it is impossible to put on the glasses found correcting the defect. A certain amount of play of accommodation must be allowed to relieve the patient from discomfort.

Dr. Dean, of Scranton, Pa., said: I have not, during this discussion, heard any one raise the question of the mydriatic producing a low grade of hypermetropia during its action in an eye otherwise emmetropic; therefore I rise to bring forward that subject. In my experience the mydriatic often produces 0.50 to 0.75 of a dioptré. Dr. Savage did say that he did not always fully correct the hypermetropia. I have had a few cases where I had glasses made with the correction with the mydriatic to change to the correction without a mydriatic.

Dr. Allen, of Pittsburg, Pa., said: I advise simple and direct methods for the examinations of the refraction of the eyes, employing the test case and test card, not regarding retinoscopy and ophthalmometry as of the greatest practical use. I examine the eye under the full effect of atropine. I have the patient wait until the effect of the atropine has passed off before the glasses are prescribed.

Dr. Zeigler, of Philadelphia, Pa., said: Referring to Dr. Jackson's paper on astigmatism following cataract extraction, I wish to place on record two cases of very high astigmatism, amounting to  $C+6$  D. ax.  $180^\circ$  in one patient and  $C+8$  D. ax.  $10^\circ$  in another. These cases occurred during my service as house surgeon at the Wills Hospital, and, notwithstanding Dr. Love's remarks I do not think there is more astigmatism under the use of the simple dressing of court-plaster, suggested by our president, and I strongly prefer the lighter dressing. I have recently refracted two presbyopes in whom the astigmatism was irregular. The last case showed  $C+2$  D. ax.  $180^\circ = C - 1.25$  D. ax.  $30^\circ$ . I desired to order  $S+3$  D. in the bifocal slip, and have had both these cylinders ground on one side of glass, leaving the other side plane for the application of the bifocal sequent. This was ground on the principle of the "tonic" lens, by Borsch of Philadelphia, and I herewith show such a lens. My habit is to use complete mydriasis for all cases under 45. The stronger solutions of atropine are used before 40 and hyoscyamine sulphate after that age. I can not rely on homatropine, and only use it when I can not avoid it. I use a solution of 16 grains to the ounce. In a recent case, aged 49, I was not

satisfied with the homatropine, and changed to hyoscyamine. While the result in one eye was the same as in the previous test, the other one showed a change in cylinder and a change in the axis. It is these occasional failures that shake our faith in the weaker mydriatics.

Dr. Young, of Burlington, Iowa, said: I desire to remind the section that twelve or fifteen years ago when I, with possibly some others present, began the study of ophthalmology we had no ophthalmometer, no skiascopy, no phorometer, no homatropine, no cocaine. We had only the ophthalmoscope, the trial case, and atropine; and yet we did creditable refractive work, creditable to ourselves under modern standards and satisfactory to our patients. Now we have all the advantages and have more trouble. Is it not due to a mistaken idea of our duty, a confusion of which we ought to know, and which we ought to do (satisfactory to the patient)? Dr. Risley properly sets up the emmetropic eye as the normal eye, but an eye artificially made emmetropic will not necessarily be a satisfactory organ practically. We should know as much as possible about it and do our work within these lines. As regards mydriatics I use the mydriatic, weak or strong, according to peculiarity of the case, to secure paralysis of the accommodation. Patients complain of discomfort from disks. I find astigmatism after extraction and have used cross cylinders in some cases for the flatter field.

Dr. Chisolm said, in response to Dr. Belt's paper, that the colored race in America was only exempt from refractive errors by absence of eye tax. Prior to 1885 colored public schools in the South were very rare. Colored children up to 15 years of age were comparatively unemployed. To eat, sleep, and play, and look after the smaller children was their occupation. So that through the growing stage there was no eye tax whatever. They escaped the dangerous period of school life which starts or develops refractive trouble. Now the colored children have all the advantage of education, and the results of their new period of eye work is that they are requiring the need of glasses also, showing conclusively that it is a fault of education more than one of race. Squint in the colored race is rarely met with. In response to Dr. Wood as to the value of mydriatic disks he would say that from neutral solutions he gets all the good and prompt action that could be desired. He uses homatropine grs. vi to 1 ounce, puts a few drops into the cul-de-sac formed by drawing the lid downward, and makes a small cup as it were, requesting the patient to look downward at the same time, so as to submerge the cornea in the liquid. He secures full action of the drug in 30 to 50 minutes. In his experience the effects begin to pass away at the expiration of an hour. Rarely does he find it necessary to use the stronger mydriatics, nor has he found any especial advantage in combining them with cocaine. In answer to Dr. Savage, he does not think it necessary to paralyze completely the ciliary muscle in his refractive work and, hence protects his patients from the annoyance of atropine instillation. He makes it a rule to cover always by glasses the entire amount of astigmatism found, but does not find that patients desire to have all hyperopia covered by plus glasses. He does not succeed in keeping his patients under observation for one or two weeks. With many of them he can only retain them twenty-four hours until the action of the homatropine has passed off, and some are not seen again after the first visit. He uses homatropine in about 30 per cent of the refractive cases. When sharp answers are elicited in reference to the astigmatic charts no mydriatic need be used. When the patient is not sure of lines or angles, or when the angle differs in the two eyes homatropine instillation is used to verify the examination. In the weaker forms of simple astigmatism, when patients have acute normal vision, but can not use their eyes with comfort, he often found that an astigmatism of 0.25 D.—would be converted into one of 0.25 D. + at right angles by the mydriatic. As soon as the mydriatic effects have passed off the myopic cylinder would be accepted as the most restful glass, and that one would be pre-

scribed. In quite a number of instances he has had to change the plus cylinder, given by others under the mydriatic, and worn with no comfort, to the minus cylinder, which was immediately restful. In the mixed cases in which normal vision without the mydriatic may be reduced to  $\frac{20}{200}$ , showing  $+6$  hyperopia and an astigmatism of not more than  $0.25 + D$ . When the effect of the homatropine has passed off they would need only a small part of the spherical strength with the cylinder, probably not half of it. I prescribe accordingly, and give much more comfort to patients than if I forced them to try to accustom themselves to the latent amount of error. In answer to Dr. Jackson he agrees with him fully that the extensive opening of the cornea for cataract extraction will in the healing act so change the corneal curvature as to cause more or less astigmatism. Most of this irregularity passes away in the course of time, so that glasses given at the end of a fortnight, the time that most of our cataract patients are dismissed, need changing in a few weeks or months. Dr. Love thinks that his patients escape these irregularities of the healing of the corneal wound by the peculiar manner of his eye dressing regulating the eye pressure and tightening the bandage after the third or fourth day after the operation. He has for many years considered the typical dressing of an eye after cataract extraction simply the closed lids, the cartilage of the upper lid acting as a splint for perfect adaptation of the corneal wound, held in position by the tonicity of the palpebral muscles. Formerly a piece of adhesive plaster perfected this result, and he still considers this the very best of eye dressing. In the past year he has laid this aside, as he found it interfering with the daily examinations of the eye, which he thinks the simple cataract extraction of the present day requires to reduce hernias of the iris should they occur. His present dressing is a single Lebright bandage to cover only the eye operated upon, to hold in position a thin pad of absorbent cotton, which makes no pressure. At the time that Dr. Love is tightening the bandage he himself removes it altogether, leaving the eye free and open. He bandages over five days, and has released the eye after two days' closure. He finds the astigmatism, nevertheless, neither more nor less than those who use much more manipulation and restraint than he does. He covers only the one eye operated upon, leaving the patient the use of the other. With Dr. Lautenbach Dr. Chisolm agrees fully as to the restricted value of the ophthalmometer. He had found it useful, and again very disappointing. The only concise work that he secures is by the trial lenses and astigmatic card, and we all acknowledge that they alone are reliable. He proceeds to their use at once, and only uses the other means and apparatus to aid should difficulties arise in the irregular responses of patients. With intelligent patients he rarely finds trouble; with the ignorant and timid we must use all the means at our hands for securing the best aid for them. There is no doubt that constant practice with any method of investigation will enable one to derive much more information than those who only use the method incidentally, and yet he feels assured that the few enthusiasts who profess to get everything out of the ophthalmometer of Javal, much more even than Javal himself contends for, are misleading the younger members of our body.

Dr. Hubbell, of Buffalo, N. Y., said: I think that most of us will agree that astigmatism almost always follows cataract extraction. How to make it as slight as possible is the question. My experience is that the greater the pressure from the dressing the greater the astigmatism that results. I aim simply to keep the eyelids closed without any pressure. I use a bandage consisting of a piece of flannel six inches long and two inches wide with a piece of tape three-fourths of an inch wide sewed to each end. One of the tapes is carried around the head over one ear under the occiput to the other tape as loosely as can be done and be kept in place. This is comfortable, very easily readjusted, and produces no pressure. I cover both eyes for the first four or five days, but do not restrict the freedom of the

patient. In the correction of refractive errors I combine the use of Javal's ophthalmometer, pattern of 1889, skiascopy, and the trial lenses. The trial lenses is the final resort in all patients who can read. The ophthalmometer has its drawbacks. A slight variation from the position of sharpest focalization, which is not always easy to determine exactly, correspondingly changes the readings on the minus. An error of 0.25 D. to 0.50 D. can thus be very easily made. Again, with the most accurate focal adjustment possible, the readings in the great majority of cases show greater refraction in vertical, or nearly vertical, meridians of the eye as compared with any other test, objective or subjective. This difference, also, is not a fixed quantity, but varies in different patients. In a very few cases by most careful use of the instrument I have been surprised to find the other tests placing the astigmatic meridian directly at right angles to that which it had indicated. The cases in which discrepancies are great are comparatively so few and positively misleading that I consider the ophthalmometer a most useful instrument, generally giving an approximate degree of astigmatism and a tolerably sure position of the meridians of greatest and least refraction. The shadow test is to me an invaluable objective method of examination. But this, too, has its weak points, although not as various as those of the ophthalmometer. In some patients the pupillary shadows do not move normally, so to speak. They either move instantaneously or irregularly, with or against the movement of the mirror when the glass is placed before the eye, which seems to be the nearest to the proper correction, and even without any glass, or, as in one case, which I recall, where the shadows moved normally in one eye, but in the other eye no shadow could be produced in any direction with or without any plus or minus glass, although the fundus could be distinctly seen with the ophthalmoscope and appeared normal, and the refraction nearly emmetropic. The vision in this eye was very amblyopic. I have no explanation for this anomalous response to the shadow test, although I studied the case carefully and with the eyes under the influence of homatropine. Again, the movements of the shadows when normal will sometimes indicate a spherical glass weaker and sometimes stronger than the patient will see best with by the subjective test. With normal shadows, however, the degree and direction of astigmatism can be quite accurately determined. The cases in which, with normal movements of the shadows, this method of examination gives results at variance with that by the subjective method are so very few that I rely upon it with great confidence, and it is most helpful, even indispensable, to me, in amblyopic patients and in children, and in others who can not read. The first thing I do in a case of suspected refractive error is to ascertain the acuteness of vision. If, without or with concave or convex glasses, I find vision equal five-fifths or better, I do not use the ophthalmometer, as I do not expect to find sufficient astigmatism for the readings of the instrument to aid me. But if the vision is below normal, especially if much below, in spite of spherical glasses I at once place my patient before the instrument with the expectation of getting some light as to whether astigmatism or some other condition is the cause of the reduced vision. If it shows astigmatism, this may be the cause, although there may be associated amblyopia; if it shows no astigmatism, I look for some other cause. If astigmatism is present, the direction is indicated and I can estimate its degree approximately. In short, in one moment it tells me in what direction to work. Its use takes so little time that I am always glad to avail myself of such suggestions as it may give, and I therefore use it constantly in the cases indicated. In testing for refraction I almost constantly use homatropine, 8 grains to the ounce of water. I always use it in practicing skiascopy, and generally in young people, even up to 48 years of age in cases of special importance. I instill a drop or two at intervals of three or four minutes for three or four times. I expect to get the full cycloplegic effect in twenty to forty-five minutes, when I proceed with

my examination. I do not believe longer time is necessary. I get such satisfactory results with homatropine in refractive work that it is very seldom, indeed, that I resort to atropine. I use the latter only in suspected cases of accommodative spasm, or in rare cases of apparent inability of homatropine to sufficiently suspend the accommodation. I consider it unnecessary, and therefore unjust and unfeeling, to inflict upon a patient the prolonged inconveniences and distresses of atropinization when the transient effects of homatropine serve the desired purpose. I determine the axis of astigmatism by using the single set of three parallel lines of proper size placed in the positions selected by the patient, and the degree of least and greatest refraction by finding the spherical glass which gives the best vision for such lines in corresponding positions. I then combine the cylindrical glass representing the difference in the two meridians with the proper spherical for one of the meridians and then direct the attention of the patient to the test letters. I seldom have occasion to modify the combination or the axis of the cylinder to secure the most acute vision. This method of determining the astigmatism is more rapid, and not less certain in its results, than any other which I have tried. In patients who give doubtful information or none at all, or who make contradictory statements as to how they see, the ophthalmometer gives some light and skiascopy affords most important and usually reliable aid. My practice is to correct all astigmatism, even small degrees in sensitive eyes, all of myopia, unless there is some special contra-indication, and all of the manifest and one-half to three-fourths of the latent hypermetropia, excepting the few cases which seem to require, for various reasons, a full correction, or a few others which insist, at least at first, on greater undercorrection. In all my refractive work I do not forget the changed relation between accommodation and convergence produced by wearing glasses.

Dr. Wood, of Chicago, said: There are several points elicited by the discussion of my paper which I desire to further elucidate. If it be true, and I do not think that the statements have been successfully controverted, (a) that solutions of the cycloplegic alkaloids in water are less effective than the same agents in oily suspension, or solid form, it must follow that homatropine disks are more effective than that drug in solution; (b) likewise if the effect of the ordinary alkaloids on the eye is increased by the addition of cocaine to them, homatropine plus cocaine is a more effective cycloplegic agent than the former alone; (c) the disk form, with cocaine, is the best one in which to exhibit homatropine when we desire to obtain its fullest effects for the determination of refractive errors. To prevent the deleterious action of the cocaine on the cornea it is absolutely essential that the eye be kept closed during the whole time that elapses between the use of the first disk and the beginning of the examination proper. The omission of this important detail is responsible for many of the failures to obtain satisfactory results with these agents. Not only is the epithelial disturbance thus reduced to a minimum, but the scleral congestion and the foreign-body feeling and smarting shortly disappear when the eye is thus kept in a state of rest. Regarding the different effects upon the symptoms experienced in the case of hyoscyamine by Dr. Risley and myself, I can only attribute them to differences in the samples supplied by our different druggists. This alkaloid in my hands has proven so uncertain and so toxic that I have entirely dismissed it from my armamentarium as a cycloplegic.

Dr. Hiram Woods, of Baltimore, said: Refractive test for ciliary paralysis after the use of a mydriatic, which I have used for some time, is to get the best distant vision and then add a weak concave glass. Myopic refraction must be previously excluded. If the best distant vision is retained with a concave glass as strong as 0.5 to 0.75 D., I do not trust the cycloplegia. I have seen total dilatation of the pupil from homatropine, and an accommodative range left of 1 D.

Dr. Jackson, of Philadelphia, said: Some accommodation may in a few cases

remain when the refraction is quite fixed. This can only be discovered by prolonging the mydriasis. When there remains voluntary accommodation, the most valuable means of detecting it is by skiascopy. The test with lenses either at a distance or near is liable to the fallacy that one part of the pupil may have one degree of ametropia and another part may have a different degree, allowing distinct vision with different lenses, although no accommodation is present. As a mydriatic I use habitually duboisine and homatropine. The former I prescribe for use in the patient's home; the latter I always instill myself, placing a drop of the 2½ per cent solution at the upper margin of the cornea. Under these circumstances, I see failure to produce complete paralysis more frequently with the stronger mydriatic. It is extremely important that the instillation should be made effectually. With reference to postoperative astigmatism, Dr. Snellen raised the point of the influence of the position of the incision. In the cases on which my paper was based, no such influence could be determined. About one-half were cases of simple extraction with the incision in the clear cornea. One-third were cases of extraction with iridectomy with the incision in the sclero-corneal junction. The remainder were cases of iridectomy for glaucoma, the incision in the extreme periphery of the anterior chamber. They were carefully studied as to the influence of the incision and the amount of astigmatism, and gave only negative evidence. The increase of hyperopia during cicatricial contraction, referred to by Dr. Hansell, was noted in a number of cases, in one the hypermetropia rose from 7 to 11 D., the astigmatism remaining 3 D. throughout. The ophthalmometer indicates that this change is mainly due to a strengthening of the antero-posterior diameter by retraction of the cornea. High tension after iridectomy, as referred to by Dr. Kollock, must be due to jamming of a large lens into the ciliary ring, and can not affect the anterior chamber while the incision remains open.

Dr. Corr said: There are three or four points in the discussion on errors of refraction and their mode of detection and correction that it seems have not been quite fully enough dwelt upon. The first of these I will put in the form of a question: Has anyone, in books or otherwise, given a standard of relaxation of the ciliary muscle or gauge by which we may know that we have obtained the desired cycloplegic condition of the ciliary muscle as a prerequisite to determining refractive errors? Dr. Wood and all others, so far as I know, who have spoken here, have referred only to the dosage, and taken into consideration, without regard to the patient's ability to, in a greater or less degree, manage or command the use of the muscle. A moment's thought will lead you to say that this can not be so implicitly relied upon. Hence some systematic plan ought to be agreed upon by which the proper condition of the muscle may be determined. Until this is done the controversy between the relative value of homatropine and atropine will be continued. I suppose each one has established some standard or gauge for his or her self, but the trouble is they do not agree; hence our results and conclusions do not agree when they should, for we are striving for the same thing amid conditions that are very similar. I will not impose on you details of varying procedure, but give my gauge or standard. After running over the case in a superficial way so as to determine the V. and the accommodative power, determining finest print the patient can read, I begin my dosage, usually homatropine 1 per cent solution, which I instill a drop every five or ten minutes for three times or oftener, after which I wait a variable time, half to one hour; then I present him a card with grades of fine print. While the patient could read medium or fine print before, he will usually say: "I can't read any on the card." Then I take a 2½ or 3 D. lens and place before his eyes, when, if that or a stronger lens only enables him to read as he read before mydriasis, I conclude that the muscle is fully relaxed. From this as a standard or gauge, I proceed to determine the error of refraction. The next point is the one of so-called "mixed astigmatism." I agree with all who may assert

it, that there are many cases of apparent mixed astigmatism, but I have never met with a case that did not, under proper mydriasis, restore itself into some simple variety or compound variety of astigmatism. The third point is the one referred to by Dr. Chisolm; that of prescribing minus cylinders axis horizontal in cases of hypermetropic astigmatism. I suspect these are the cases of mixed astigmatism referred to, and involves the question as to whether you would prescribe a minus cylinder axis horizontal in a case where there is simple hyperopic astigmatism in horizontal meridian. Another point that I think should be emphasized more definitely is that, according to circumstance, of requiring the patient to wear a full correction. I think this ought to be insisted upon in many cases as importunately as is agreeable. As is well known, the distant vision is not so good for a variable length of time with the full correction. Of this the patient ought to be advised, that the medicine must be taken for awhile, bad as it is, and soon it will taste better. Here another point suggests itself, that of whether we should lead our patients to expect a cure of their eye discomfort, or headache, or whatever led them to seek advice except amblyopia, so they will not always need to wear the correction. I have seen cases of perpetual and torturing headache for many years so far cured that they could leave off the correction, still pursuing their studies or business with immunity for years.

Dr. Savage, of Nashville, Tenn., said: My advocacy of the complete suspension of the accommodation of the operator, as well as of the patient. A full knowledge of the error should be had, not that in all cases a full correction should be given, but that a correct record should be made. The "balance" of the lateral muscles should determine if no correction, a partial, or a complete correction of the focal error is to be made. And let me insist that these cases be tested when the eyes are uninfluenced by the mydriatic. As to the correction of astigmatism, this can be done in any case by either plus or minus cylinders, the one increasing the refraction of the least refractive meridian, the other decreasing the refraction of the greatest refractive meridian, and in either case the astigmatism is corrected. Knowing the existence of a lateral muscle error, but ignoring its treatment, we should be guided by this knowledge in prescribing plus or minus cylinders. If there is hypermetropic astigmatism associated with exophoria a minus cylinder correcting the astigmatism would add to the patient's comfort, while a plus cylinder would increase his discomfort. If the hypermetropic astigmatism should be associated with esophoria it would be folly to correct the astigmatism with a minus cylinder, for it would make the patient worse. The correct thing to do would be to treat the muscle error and cure it, either by operation or exercise, and then prescribe the lenses indicated by the state of the refraction. I am asked if a mydriatic is not necessary in our study of cases of mixed astigmatism? It is, but not more so than in the other forms of astigmatism. We may have a case appearing to be mixed astigmatism, which the mydriatic will show to be hypermetropic, simple or compound. On the other hand, we may have a case of apparently myopic astigmatism, simple or compound, which the mydriatic would show to be mixed astigmatism. Mixed astigmatism is so rare that a man's reputation may suffer who fails to find it when it exists, or supposes he has found it when it does not exist. The mydriatic can alone make him certain. If he should find it he should tell the patient of it; and if he does not give the mixed correction he should give his reasons to the patient. Otherwise when the patient drifts into the hands of some confrère, he may remark: "I have always considered Dr. — a competent man, but he missed it badly in your case." It is always best to know the refractive error and to correct it, or give the patient some good reason for not prescribing a full correction. To the question just asked by Dr. Corr, "Do glasses scientifically prescribed relieve the symptoms, headaches, etc., commonly attributed to eye strain," I will answer by reporting a case that has come under my observation. The patient not only suffered

with headache but was also an epileptic. I was asked by the physician in charge of the case to examine the eyes and correct any error found, with the hope of a cure. It was agreed that the patient should not be told that we suspected that anything like a causative relation existed between the eyes and the epileptic attacks. I found 4.50 D. hypermetropia in one eye and 5 D. in the other, with slight astigmatism in each. This was seven years ago, when I was not a believer in muscle troubles, hence did not then know that this patient had an esophoria. I fortunately prescribed a full correction. The glasses were worn more or less continuously four years, with relief from headaches and epileptic seizures. Not having been impressed that the glasses had brought this relief, the patient began to leave them off, and finally ceased wearing them. The epilepsy returned and, strange to say, the glasses were still neglected. Four months ago the new family physician in getting a history of the case, learned of the wearing of the glasses and the coincident immunity from suffering. He sent the case to me for investigation again. I did not reexamine the focal condition. Having in the meantime learned something of heterophoria (thanks to Dr. Stevens who made this study a possibility, and thanks to my good fortune that I stumbled into this study even as early as I did), on investigation I found 4 degrees of esophoria about the same for near and distant vision. On placing the full focal correction before the eyes I found that both the focal and the muscular error was corrected by them. This I expected from my knowledge of the relationship between the centers of accommodation and convergence. For the first time I told the patient that the epilepsy was due to errors of the visual apparatus which the glasses corrected; and I gave assurance, based on four years of relief by wearing the glasses, that these would cure in that they would remove the cause. There have been no other attacks nor do I expect any so long as the glasses are worn.

Dr. P. Lagleyze, replying to Dr. Savage, said: Algunos oculistas emplean indif-erentemente los midriáticos para la corrección de cualquier vicio de refracción. El diámetro de la pupila ejerce una acción considerable sobre la agudeza visual, porque las dimensiones de los círculos de difusión están en relación directa con el grado de dilatación pupilar.

El diámetro de la pupila no influiría mucho sobre la nitidez de la imagen, á pesar de la aberración de esfericidad y de refrangibilidad que poseen todos los ojos, si la córnea fuera esférica. La córnea tiene una forma elipsoidal y según las últimas medidas practicadas por Sulzer, resulta que si se pasa del centro á la periferie, la curvatura disminuye irregularmente, no solo á lo largo de los dos meridianos principales, sino aún á lo largo de las dos mitades del mismo meridiano. Esta disposición es causa de diferencias entre la refracción central y la de las partes periféricas. Se concibe, pues, que la atropina, permitiendo que las partes periféricas de la córnea participen en la visión, produzca variaciones, y por consiguiente que el vidrio corrector elegido en estas condiciones no sea el más conveniente.

En los hipermétropes, en general, no debe recetarse lentes bajo la acción de la atropina; el hipermetrope, por el hábito de acomodar constantemente ha establecido una armonía difícil de alterar entre su convergencia y su acomodación, empleando una parte ó toda su amplitud relativa de acomodación positiva binocular.

Sin embargo, no debe desecharse en absoluto el uso de los midriáticos; hay casos, en que llena una indicación, por ejemplo, cuando se sospecha una contracción irregular de la acomodación y tambien en los espasmos ciliares de todo el músculo.

Some oculists employ indifferently mydriatics for the correction of any vice of refraction. The diameter of the pupil exercises considerable action on the visual sharpness, because the dimensions of the circle of diffusion are in direct relation with the degree of dilatation. The diameter of the pupil would not influence much the clearness of the image, notwithstanding the spherical and refractive observation that all eyes possess, if the cornea was spherical. The cornea has an ellip-

soidal form, and according to the latest measurements practiced by Sulzer, it results that if it passes from the center to the surface the curvature diminishes irregularly, not only in length of two principal meridians, but also in the two halves of the same meridians. This arrangement causes the difference between the central refraction and that of the peripheral parts. We conceive, then, that atropine, allowing that the peripheral parts of the cornea participate in the vision, produce the variation and therefore that the correcting glass selected in these conditions is not the most convenient. In hypermetropia in general, glasses must not be prescribed when under atropine influence. The hypermetropia, by the habit of constantly accommodating has established a harmony difficult to change between its convergency and accommodation, employing a part or the whole of its relative amplex for positive binocular accommodation. Yet, the use of mydriatics must not be put aside absolutely. There are cases, for example, when an indication has been filled, when we suspect an irregular contraction of accommodation and also in ciliary spasm of the whole muscle.

Dr. Belt, of Washington, D. C., said: In reference to Dr. Jackson's paper on astigmatism following cataract extraction, I am inclined to think that a large amount of astigmatism is due in our prescribing glasses and allowing the use of the eyes for reading too soon after the extraction. The patient having been blind for some time is impatient to see to read and work, and wants his glasses as soon as possible, and when he gets them he thinks he should be able to read with as great facility as ever, and when he finds he can not do that, by great effort tries to bring to his aid the external muscles and lids, and this great pressure on an eyeball, still weak and pliable when the corneal section was made, cause the astigmatism. This is probably counteracted later by contraction of the wound by cicatrization, thus decreasing the astigmatism. However, astigmatism may develop a year or two after extraction; e. g., in a case operated upon by me about two years ago, three months after extraction vision was  $\frac{20}{80}$  with 10 D., three months later a 1 D. cyl. ax.  $180^\circ$  was required to give that vision, and a year later a 2 D. cyl. ax.  $180^\circ$  was required. In reference to the disks of homatropine and cocaine as recommended by Dr. Wood, I tried disks of homatropine, thinking they would be convenient for the patient to use an hour before coming to my office so I could proceed at once with the examination, but usually found as a result conjunctival irritation sufficient to interfere with the examination, so I have gone back to the use of solutions. I think the combination with cocaine objectionable, owing to its causing dryness of the epithelium, which prevents clear perception. Dr. Kollock called attention to the cases of corneal disease found by me among the colored pupils. Knowing its prevalence generally in the race, I can only account for it by the carelessness of negro parents in allowing children, even with slight troubles, to remain at home. I did not pay especial attention to the question of whether the cases of strabismus found in the colored pupils were among the mulattoes or the pure-blooded negroes.

Dr. Chisolm said: To-day we take up the subject of muscle errors. We have been a long time finding out that the extraocular muscles, numerous and large as they are, should necessarily play a very important rôle in the comfort and discomfort of eye work. I can not say that we have devoted too much time to the study of refractive errors, for ciliary muscle action is undoubtedly the pivot for acute. But to keep the fovea centralis in its proper place, to secure binocular vision, is the duty of the recti and oblique muscles. It requires that these six pairs of muscles be nicely adjusted and always alert, for they are in perpetual action during our wakeful hours. Lately I have been devoting much more time in exploring the individual functions of each of these muscles, and am quite sure that results are against my former neglect. I hope that the discussion will elicit much knowledge for our future guidance in a class of cases which becomes quite numerous the more carefully we seek them.

## A CLINICAL STUDY OF HETEROPHORIA.

By Dr. HIRAM WOODS, of Baltimore, Md.

I fear my paper may seem to some surgeons too elementary ; reactionary rather than progressive. Most of the articles one meets nowadays in journal literature on heterophoria show, it seems to me, a tendency toward a refinement of diagnosis and treatment, proper enough in itself and under certain circumstances, but not reaching the question which daily puzzles an oculist in office work. "What is the significance of the heterophoria in the case before him?" Text-books of eight or ten years ago give little or no information. Those by American authors of more recent date discuss the subject more or less fully; but I doubt if Dr. Noyes, or Dr. de Schwenitz, or other recent book writers, would claim that their chapters on muscularas thenopia are more than pointers for original investigation. The more I see of heterophoria the more I appreciate the truth of a recent remark by Dr. Stevens (*Ophthalmic Record*, January, 1892): "One will find himself too often in the face of serious embarrassments to believe that he has arrived at the knowledge of an easy system in which all the ultimate facts are at his command." I am often in doubt whether to lay stress upon the refraction and accommodation or upon the muscular anomaly; whether to regard the latter as really the cause of the asthenopia headache or other disturbance which has brought my patient to me, or as only symptomatic and secondary, a guide, so to speak, to the real cause. This question lies at the bottom of every case. It can not be answered by the amount of equilibrium error; for, if my experience has taught me correctly, fractional degrees sometimes cause trouble, and high grades frequently do not. I wish to present in this paper a few clinical observations in the hope that they may call from those better acquainted with the subject a profitable discussion. I have nothing new to offer; only a study of the findings by methods in common use.

For four or five years I have realized the importance of examining the condition of the extrinsic eye muscles. Cases of asthenopia I could not relieve, no matter how carefully I corrected the refraction. I consulted others with the same result. I first turned my attention to the subject in a practical way. I began work by causing diplopia at 20 feet by holding a square prism in front of the eye. For two years or more I have used Maddox's double prism, with a colored glass before one eye, and more recently his rod. Before examining the muscles, I correct the refraction, giving as nearly the full correction as is consistent with the best visual acuity. I note abduction. If the equilibrium test has shown orthophoria and abduction is  $10^{\circ}$  or  $12^{\circ}$ , I suspect "latent" exophoria, as it has been called. If it is below  $5^{\circ}$ , I suspect "latent" esophoria. I am skeptical about adduction. In the first place, as has been pointed out by others, it is a distance test only so far as convergence can act independently of accommodation: i. e., to the extent of the positive portion of the relative range of convergence for infirmity, Dr. Randall (*Trans. Am. Ophth. Soc.*, 1889) says: "Adduction can be made almost anything, if the patient and examiner have patience." It is striking how rapidly adduction increases as soon as the patient learns how to fuse images of unequal clearness. I have seen adduction of  $48^{\circ}$ , while the balance test showed exophoria of  $10^{\circ}$ . Its determination is not, in my opinion, important unless one is contemplating an internal tenotomy for esophoria, when it is well to know that adduction can be developed to a point higher than the normal relation to abduction.—7 or 8 to 1.

Unless the equilibrium test has shown hyperphoria, I do not, as a rule, examine the power of the vertical muscles to overcome opposing prisms. I look upon comparison of the distance and near equilibrium as very important. Except in the case of presbyopia, or where there are, in myopia, conditions which demand special modification of the glass for near work, the near test should be made with distance glasses. What relation should the near equilibrium bear to the distance?

Dr. Noyes (*loc. cit.*) says that "most commonly there is a deviation (from the vertical) in the sense of abduction of about  $5^{\circ}$  which can not be called abnormal." Dr. Randall (*loc. cit.*) thinks that insufficiency of convergence for the near is the rule among hypermetropes, because the hypermetrope can avoid excessive convergence only by utilizing and developing the negative part of his range of relative convergence and \* \* \* the correction is overdone." Again, two years later before the same society, in discussing a paper of Dr. Theobald's, he said that while this convergence insufficiency at the near was the rule rather than the exception, he could not accept it as normal any more than he could "accept as normal the hypermetropia which is present in the majority of eyes." As to the frequency of this near divergence, compared to the distance balance, 100 consecutive cases from my case book show: Equilibrium the same at 13 inches as at 20 feet, 16; comparative divergence at 13 inches, 81; comparative convergence at 13 inches, 3; total, 100.

The distance equilibrium of the 100 was, orthophoria, 39; esophoria, 29; exophoria, 28; hyperphoria, 3; hyper-exophoria, 1. This condition was noted in 23 of the 39 with distance orthophoria; 26 of the 29 with esophoria; all the 28 with exophoria; and the 4 with vertical deviation. I do not think another 100 would differ materially from this. It is clear that the condition is so very frequent as to be almost constant, and is not confined to any form of distance equilibrium. Regarding the associated refraction of these 82 cases, 54 were hypermetropic; an apparent confirmation of Dr. Randall's statement that it occurs most frequently in hypermetropic refraction. Myopic refraction was noted in 21 of the 82, with near divergence. Of the entire number (100) 66 showed hypermetropic and 26 myopic refraction. Thus a divergence at 13 inches, relative to the equilibrium at 20 feet, was noted in 81.8 per cent of persons with hypermetropic and 80.8 per cent of persons with myopic refraction, a difference of 1 per cent only. These figures would seem to indicate that divergence at 13 inches is seen most frequently in hypermetropia, because hypermetropia is the most common form of refractive error. Is this divergence at the near compared to the balance at 20 feet normal? Can we make any useful inference from a departure from it? In my opinion we can, and I daily use it as a guide in my refraction work.

Dr. Samuel Theobald presented a paper to the American Ophthalmological Society in 1891, entitled: "Subnormal accommodative power in young persons a not infrequent cause of asthenopia." The objective point of the paper was to show that young persons often became asthenopic without refractive or muscular error; that others continued so after the correction of these errors, and that the cause lay in a subnormal accommodative power, whether a weak ciliary muscle or a lens incapable for one reason or another of responding to ciliary action. It was pointed out that the usual symptoms of presbyopia did not exist in this condition, but that the diagnosis lay in the relation of the equilibrium test at 13 inches to that at 20 feet. He looked upon a comparative divergence at 13 inches of  $2^{\circ}$  to  $5^{\circ}$  as normal. The near balance might depart from this in the direction of excessive or deficient divergence. Excessive divergence might come from myopia through the correlation of the functions of accommodation and convergence. Dr. Theobald thought that low exophoria which appeared as orthophoria at 20 feet could cause the same excessive divergence at 13 inches. The exclusion of this, I think, would be very easy. There are cases of exophoria which for a time appear as distance orthophoria, but they generally are accompanied by abduction of  $10^{\circ}$  to  $12^{\circ}$  or the retention of the orthophoria balance at 20 feet with an abducting prism. The third cause of comparative divergence over  $5^{\circ}$  was a hypersthenic ciliary muscle, calling for less nerve force, and so causing less nerve force to the internal rectus. Departure from this "normal" comparative divergence of  $2^{\circ}$  to  $5^{\circ}$  in the direction of deficient divergence could come from any condition which might call for excessive nerve stimulation to the ciliary and so to the internal

rectus muscle. Uncorrected hypermetropia, a weak ciliary muscle, or an unresponsive lens, demanding more than normal ciliary action, are such conditions. Hypermetropia can easily be excluded. Esophoria, by lessening the amount of opposition to the interni, might also cause it; but if the esophoria is not disclosed by the equilibrium test at 20 feet low abduction or the retention of orthophoria with an adducting prism would lead us to suspect it. Thus we are left with the subnormal accommodative power. The conclusions drawn by Dr. Theobald are (1) comparative divergence at 13 inches of  $2^{\circ}$  to  $5^{\circ}$  is normal; (2) in the absence of the other possible causes, which can be excluded, a comparative divergence greater than  $5^{\circ}$  means hypersthenia of the ciliary muscle, less than  $5^{\circ}$  subnormal accommodative power.

A word concerning this near test as modified by refraction correction. (1) The relation holds only when the near test is made with the eyes behind the same glasses worn during the distance test. In compound hypermetropic astigmatism, for instance, after mydriasis has disappeared the hypermetropia often becomes latent, the cylinder alone being accepted. The addition of a spherical, correcting any part of the latent hypermetropia, increases the comparative divergence. A case in point:

March, 1893; Mrs. C., 22 years old; eye pains and headache on reading. Under homatropine right eye attained  $\frac{20}{40}$  with  $+1.5$  S.; left eye attained  $\frac{20}{40}$  with  $+1.25$  S.  $\subset +0.75$  C.  $90^{\circ}$ . Three days later right eye, Hm.  $+0.75\frac{20}{40}$ ; left eye, As. Hm.  $+0.75$  C.  $90^{\circ}\frac{20}{40}$ ; muscle 20 feet, esophoria,  $3^{\circ}$ , Ab.,  $5^{\circ}$ , near esophoria,  $3^{\circ}$ ; no comparative divergence at all at 13 inches. By adding the spherical equivalent to the latent H., near orthophoria was obtained, but distant vision was reduced to  $\frac{20}{40}$ .

A message from this lady two weeks ago was to the effect that these glasses had completely relieved her. My reason for neglecting the esophoria in treatment was the nearly normal abduction ( $5^{\circ}$ ). I felt reasonably sure that it was secondary to the uncorrected refraction error, which was of such a nature as to cause excessive internal rectus action. In this comparative divergence I find a guide to the correction of latent hypermetropia. I believe that the nearer we come in our refraction work to an emmetropic correction, the more positive and permanent will be the relief. But the correction of latent hypermetropia often relieves distant vision, and, in low compound hypermetropic astigmatism, especially, the correction of the astigmatism alone frequently relieves. While these are exceptions, I believe a safe rule is to correct enough latent hypermetropia to produce at 13 inches a comparative divergence if  $2^{\circ}$  or  $3^{\circ}$ .

(2) In myopia of 3 or 4 D., if the correcting distance glass be employed at 13 inches, there will nearly always be deficient comparative divergence, disappearing when the strength of the concave is reduced. I believe this is due to the habitual non-use of the ciliary muscle.

I have for the past two or three years been in the habit of training young myopes with normal visual acuity and good fundus to wear their total correction, provided it does not exceed 5 or 6 diopters. Reading for a time is difficult, but the ciliary muscle soon learns to work, and the usual comparative divergence at 13 inches develops. Esophoria contraindicates the use of the strong concaves for near, I think, because of the necessarily increased ciliary, and so internal rectus activity. But esophoria and myopia of any degree are not frequently associated.

I have dwelt thus at length upon the relation of the near to distance equilibrium because I am inclined to think there is a tendency to underrate the value of the near test. It is useless as a test for muscular equilibrium; but if its relation to the distance balance has such significance as Dr. Theobald has given it it is useful not only as a diagnostic sign of subnormal accommodative power, but as a guide in the treatment of at least one form of heterophoria, viz, esophoria. If this condition occurs, as it usually does, with hypermetropic refraction, the indication would be to correct all or nearly all of the hypermetropia, and the more nearly the 13

inches balance corresponds with that at 20 feet the more of the hypermetropia should be corrected. I have already spoken of esophoria contraïndicating strong concaves at the near. When there is no refractive error, and the esophoria is to be attacked independently, an excess of near divergence indicates a weaker adducting prism than if the comparative divergence is of the usual degree or deficient. In esophoria, prisms, according to my experience, give us their best results, and this guide to regulating their strength is with me not a mere theory. Contradictory findings by the various tests are a common cause of perplexity.

Different results may be gotten at different sittings; the equilibrium tests and the power of the muscles to overcome opposing prisms may not harmonize. Such things Dr. Stevens has attributed to hyperphoria. That this variety of heterophoria does influence the others can not be doubted. I want to mention two or three cases, however, which show, I think, how close the connection is between anomalies of the ciliary muscle and anomalous heterophoria.

Mr. G., 28 years old, consulted me in April, 1890. He was unable to work comfortably at his desk in the post-office. He was wearing — 0.25 C. 180° with  $\frac{2}{15}$  D. V. He rejected all convex glasses. He had orthophoria at 20 feet with ab. of 12°. A near test was not made at that time. Under atropine his apparent low M. As. was turned into compound H. As., each eye accepting +1 S.  $\subset$  +0.5 C. 90°. As mydriasis wore off, convex glasses reduced vision to about  $\frac{2}{40}$ . Minus cylinders at once cleared vision, but he found he could work better with the convex glasses. For a year or so he called to see me occasionally. He always had orthophoria and high abduction 10 to 12°. He gradually got  $\frac{2}{20}$  with his glasses and still more gradually developed an exophoria, which in the end amounted to 6°. He has since then worn prisms 2°, bows in, combined with his refraction correction, and is comfortable.

This seems to me to be a case of exophoria concealed by an excessive innervation of the weak muscle, associated with ciliary spasm. An abduction too high for the equilibrium was the only indication. The exophoria was, I believe, a factor in producing the ciliary spasm. My assistant at the Presbyterian Hospital called my attention a few months ago to the case of a seamstress 23 years old who had had only  $\frac{1}{40}$  V. when he first examined her. Improved by minus glasses. Homatropine gave her  $\frac{1}{30}$ , and atropine, used for several days, had brought her to  $\frac{1}{15}$  with a +0.75 S. The girl had persistent headaches and the refraction did not account for either them or this ciliary condition. The equilibrium test at 15 feet showed exophoria of 9° with abduction of 10°. The explanation seemed clear; exophoria with secondary ciliary spasm. I have seen several such cases as these, but it is useless to narrate them.

The points I desire to make are that a contradiction between equilibrium and abduction requires careful investigation; that a weak internal rectus may produce ciliary trouble, and this contradiction be the only clue to the real cause. Neither of these cases had any manifest or latent vertical deviation.

A second anomalous finding I have met at 20 feet is exophoria, with normal abduction.

Mr. W., 22 years old, student, was first seen in 1887. He was unable to work over half an hour without pain. Glasses had so far failed to relieve him, though selected by a competent man. His refraction under atropine was, right eye,  $\frac{2}{20}$ , with — 2.25  $\subset$  — 0.5 C. 45°; left eye,  $\frac{2}{20}$ , with — 4 S.  $\subset$  — 0.75 C. 180°. The muscle test at 20 feet was exophoria 4°, ab. 6°, ad. 24°; at 13 inches, exophoria 4°, same as at 20 feet. The amplitude of accommodation was only 2.5 diopters. He was given the full correction for the right eye for distance, with the same spherical correction over the astigmatism for his left. On account of his weak accommodation, only the cylinder was ordered for his best eye (the right), the cylinder and — 0.75 S. for left. He read at 13 inches with these, either eye. For a time he was better, and then the old symptoms returned. Not to prolong the case, after two years' of tonic, electric, and other time-wasting methods of treatment, advised by myself and others, it was decided to get rid of the exophoria. I did external tenotomy. At first an esophoria of 3° resulted, but in a few days orthophoria was found. The therapeutic results were absolutely nil. Work over 15 minutes was an impossibility. In a year (1890) there was the old muscular condition.

At my suggestion Mr. W. went to New York in the fall of 1890 and consulted Dr. David Webster. Dr. Webster expressed the opinion that everything had been tried except to make the accommodation work. He advised full correction on both eyes for all work. Mr. W. put on his glasses, and for nearly two months held his reading (when he did any) at arm's length. His discomfort was greater than ever. Still he persevered, and gradually his p. p. came within respectable limits. His condition now is, to use his own words, "as good as it probably will ever be." He can read and write for several hours, and follows his occupation of civil engineer. His exophoria has disappeared at 20 feet and his abduction is  $6^\circ$  at 13 inches; he has  $1^\circ$  to  $2^\circ$  of exophoria. Here, it seems to me, was a case of weak ciliary muscles. Because of the myopia they did not receive the extra nerve force spoken of, and so the internal recti did not receive it either. The result was pseudo-exophoria, and the normal abduction should have been a clue.

A third anomalous finding at 20 feet, which I have noticed in connection with hypermetropic astigmations, especially against the rule, is esophoria with normal or even high abduction. Time will not allow me to cite the cases in detail. Suffice it to say that they usually show deficient comparative divergence at 13 inches, and that the esophoria nearly always disappears after the correcting cylinders have been worn for a time. Their explanation is to be found, I believe, in the excessive and irregular action of the ciliary muscle called out by the uncorrected refractive error.

I would not be understood as expressing a doubt that all kinds of heterophoria can cause distressing asthenopia; that even when refraction errors exist, the muscular error may be the most important element. I have had, myself, a personal experience with esophoria, and know how to appreciate the value of adducting prisms, and later, the internal tenotomy which my friend, or Harlan, did for me last March. But in the cases such as I have narrated, where one test contradicts another, I believe it behooves us to move slowly; to find the underlying cause by patient, repeated investigations before we put on prisms, except for diagnosis; proceed with exercise, or do tenotomy. I believe this cause is found in the accommodation or the associated refraction error more commonly than is generally thought, and that frequently muscular perplexities will clear up behind spherical or cylindrical glasses. When there is nothing found of importance except the muscular error, it is foolish to delay. I should like to discuss some other points, but I can do nothing more than mention them. I have not met hyperphoria as often as some others seem to meet it, but I have seldom seen it exist to the extent of  $1\frac{1}{2}^\circ$  or  $2^\circ$  without requiring treatment. I have had in a few patients to correct, by prisms, as little as  $\frac{1}{2}^\circ$  or  $\frac{3}{4}^\circ$ , and with good results, after refraction correction had failed to relieve. Again, I believe there is a good deal in the association of certain refraction errors and different forms of heterophoria. Hypermetropia and exophoria, myopia and esophoria, low degrees of heterophoria and astigmatism against the rule, have seemed to me specially troublesome combinations.

There are certain symptoms which I think characteristic of muscular asthenopia. They are mentioned in Dr. Noyes's book, and in my own case I have noted them, I am sorry to say, in an emphatic way, a sense of tension while reading, occasional paroxysms of pain in the eyeballs, lasting sometimes two or three hours, pain on awakening in the morning, and an indefinite, but, as I know by experience, positive symptom which a gentleman a short time ago thus described to me: "My eyes just won't work any more," i. e., a sudden collapse while at work. Such symptoms, I believe, are usually due to the muscular anomaly.

To review the entire subject of heterophoria in one paper is an impossibility, and I must leave the question of treatment almost untouched. By exercising the weak muscles with prisms I have gotten good results in a few cases of exophoria, but in the other forms of heterophoria I have found it useless. I am now trying Dr. Savage's "rhythmical exercise," but can not yet say much about it. Prisms have

given me best results in esophoria and very low degrees of hyperphoria. I have never done tenotomy for less than 6° of esophoria, 4° of exophoria, and 2° of hyperphoria. I have always done complete tenotomy. The operation, in some instances, where the error was low, was undertaken only after other treatment had failed. It was "complete" only because repeated examinations during the "partial" stage failed to show any equilibrium gain. I know it is behind the times to say so, but I have never noted any change in the equilibrium test at 20 feet until I thought I had severed the entire tendon. I meet cases in practice where prisms are not tolerated. Evidently the muscular anomaly is causing the trouble, and I know there is not room for a complete tenotomy. I hope to get some light on this question to-day.

### AN ANALYSIS OF FIFTY SUCCESSIVE CASES OF INTERNAL SQUINT.

By HOWARD F. HANSELL, M. D.,

*Chief of Ophthalmic Clinic, Jefferson Medical College Hospital; Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic.*

TABLE OF CASES.

| No. | Sex. | Age. | Age when noticed. | Fixing eye. | Refraction (under myd.) of right.   | Refraction (under myd.) of left.    | Vision of right. | Vision of left. |
|-----|------|------|-------------------|-------------|-------------------------------------|-------------------------------------|------------------|-----------------|
| 1   | F.   | 17   | 3½                | L.          | + 4 $\ominus$ + 2 c. ax. 90°.....   | + 4 $\ominus$ + 1.75 c. ax. 90° ..  | $\frac{6}{80}$   | $\frac{5}{75}$  |
| 2   | F.   | 25   | 12                | R.          | + 1 $\ominus$ + 3 c. ax. 80°.....   | + 1 $\ominus$ + 3 c. ax. 100°.....  | $\frac{6}{60}$   | $\frac{5}{15}$  |
| 3   | F.   | 23   | 3½                | R.          | + 3 .....                           | + 5 (estimated).....                | $\frac{6}{60}$   | $\frac{2}{60}$  |
| 4   | F.   | 8    | 1½                | L.          | + 4 $\ominus$ + 1 c. ax. 135°....   | + 4 $\ominus$ + 1 c. ax. 45° ....   | $\frac{6}{75}$   | $\frac{5}{75}$  |
| 5   | F.   | 3½   | (1)               | R.          | + 2 .....                           | + 2 .....                           | (2)              | (2)             |
| 6   | M.   | 45   | (3)               | R.          | + .25 $\ominus$ + .50 c. ax. 90° .. | + 3 (estimated).....                | $\frac{6}{60}$   | $\frac{1}{60}$  |
| 7   | M.   | 22   | 4                 | L.          | + 1.75 $\ominus$ + 3 c. ax. 70°..   | + 3 $\ominus$ + 1 c. ax. 110° ...   | $\frac{6}{60}$   | $\frac{6}{60}$  |
| 8   | F.   | 13   | 3                 | L.          | + 3 .....                           | + 3.25 $\ominus$ + .25 c. ax. 90°   | $\frac{6}{60}$   | $\frac{6}{60}$  |
| 9   | M.   | 14   | 4                 | R.          | + 1.25 $\ominus$ + .25 c. ax. 90°   | + 1.25 $\ominus$ + .25 c. ax. 90°.  | $\frac{6}{60}$   | $\frac{6}{60}$  |
| 10  | M.   | 10   | 6                 | R.          | + 3 $\ominus$ + 3 c. ax. 80° .....  | + 3 (estimated) .....               | $\frac{6}{15}$   | $\frac{1}{60}$  |
| 11  | F.   | 6    | 3                 | R.          | + 1.25 $\ominus$ + .50 c. ax. 90°   | Irregular astig .....               | $\frac{6}{75}$   | $\frac{6}{60}$  |
| 12  | F.   | 6    | 2                 | R.          | + 2.50 .....                        | + 2.50 .....                        | $\frac{6}{15}$   | $\frac{1}{15}$  |
| 13  | F.   | 4    | 3                 | R.          | + 2 .....                           | + 2 .....                           | $\frac{6}{75}$   | $\frac{6}{75}$  |
| 14  | F.   | 15   | 6                 | R.          | + 4 $\ominus$ + 2.25 c. ax. 180°.   | + 4 $\ominus$ + 1.25 c. ax. 135°.   | $\frac{6}{60}$   | $\frac{20}{20}$ |
| 15  | M.   | 7½   | 6                 | R. or L.    | + 4 $\ominus$ + 1 c. ax. 45°.....   | + 4.75 .....                        | $\frac{6}{10}$   | $\frac{1}{10}$  |
| 16  | M.   | 8    | (1)               | R.          | + 3.50 .....                        | + 6 .....                           | $\frac{6}{60}$   | $\frac{1}{60}$  |

<sup>1</sup> Birth.

<sup>2</sup> Unknown.

<sup>3</sup> Childhood.

<sup>4</sup> Illiterate.

Inspection of the series of cases shows:

1. That convergent strabismus is most common between 2 and 4 years of age (36 per cent). The earliest age at which it was noticed was at birth (4) and the latest at 15 years (1).

2. Females preponderate over males as 31 to 19.

3. The right was the fixing eye in 20, the left in 18, and either eye was used indifferently in 12 cases.

4. The refraction was hypermetropia in 92 eyes; 2 had myopia, probably acquired through corneal inflammation; 4 had comp. M. As., with full acuity of V.; 2 had hyperopic astig. with one-half V. The fixing eye showed simple H. in 16; comp. H. in 21 cases. Of the former H. was less than 2 D. in 3; between 2 and 4 in 10; between 4 and 6 in 2, and above 6 in 1 case. Of the latter the comp. H. As. was less than 2 D. in 4; between 2 and 4 in 7, and higher than 4 in 10; defect unrecorded in 1. The squinting eye showed simple H. in 18, comp. H. As. in 15. The former H. was less than 2 D. in 1; between 2 and 4 in 12; higher than 4 in 5. Of the latter comp. H. was less than 2 D. in 1; between 2 and 4 in 2; higher than 4 in 12. Twelve cases used either eye indifferently for fixation; of these there was no case of simple H. in both eyes; 2 had comp. M. As. of low degree; 3 had comp. H. As. of less than 2 D.; 3 between 2 D. and D., and 4 between 4 D. and 6 D.

5. Vision in the fixing eye after correction equaled 1 in 21,  $\frac{2}{3}$  in 9,  $\frac{1}{2}$  in 4, and  $\frac{1}{3}$  in 2 cases; unknown in 2. V. in the squinting eye after correction equaled 1 in 2,  $\frac{2}{3}$  in 4,  $\frac{1}{2}$  in 8,  $\frac{1}{3}$  in 2,  $\frac{1}{5}$  in 3,  $\frac{1}{10}$  or less in 10 cases; unknown in 2. Of the 12 cases in which either eye was used indifferently V.=1 in 7,  $\frac{2}{3}$  in 3,  $\frac{1}{2}$  in 1,  $\frac{1}{3}$  in 1 case.

An examination of the notes of 200 consecutive cases (400 eyes) of H. and H. As. greater than 1 dioptré abstracted from my private case book, uncomplicated by disease and without squint, in relation to the degree of ametropia and to the vision obtained by full correction (under mydriasis), shows: H. and comp. H. As., between 1 D. and 2 D. in 98, between 2 D. and 3 D. in 40, between 3 D. and 4 D. in 17, between 4 D. and 5 D. in 13, higher than 5 D. in 9 cases. Also 23 cases in which H. of one eye exceeded that of the other by 1 dioptré or over, with a difference of one-third or more in the acuity of vision. V. = 1 in 310,  $\frac{2}{3}$  in 24,  $\frac{1}{2}$  in 11,  $\frac{1}{3}$  in 12,  $\frac{1}{5}$  or worse in 43.

My purpose in this brief analysis and comparison is to prove clinically that:

1. H. is found in nearly all cases of internal squint. Ninety-two eyes of the series had hypermetropic refraction.

2. H. is not essential to convergent strabismus. Two cases, Nos. 20 and 25, had low myopia.

3. Congenital amblyopia is almost uniformly present in constant internal squint. Amblyopia in this connection means decidedly diminished vision from no known cause without pathological changes and not correctible by glasses. In 38 squinting eyes V. = 1 in 2,  $\frac{2}{3}$  in 4,  $\frac{1}{2}$  in 8,  $\frac{1}{3}$  in 2,  $\frac{1}{5}$  or less in 19 cases; unknown in 3. The exceptions—where V. = 1—were Nos. 9 and 33, evidencing no reason why one eye should invariably be used for fixation.

4. Amblyopia is not essential to squint, either constant or alternating. Cases Nos. 9 and 33 are illustrations of constant squint without amblyopia, and Nos. 20, 21, 25, 26, 28, and 49 of alternating squint with full V. in each eye.

5. Amblyopia is found in H. without squint. Among the 200 cases of H., V. was equal to one-half or less, without known cause in one eye and normal in the other in 9. Two cases serve to illustrate this statement: No. 1. Female, age, 46: R. + 7  $\odot$  + .50 c. ax:  $45^\circ = \frac{6}{30}$ ; L. + 7  $\odot$  + .50 c. ax:  $135^\circ = \frac{6}{30}$ . No. 2. Female, age, 45: R. + 3  $\odot$  + 2 c. ax:  $35^\circ = \frac{6}{30}$ ; L. + 3  $\odot$  + 3 c. ax:  $90^\circ = \frac{6}{30}$ . Instances of nearly identical ametropia with amblyopia among the cases of squint Nos. 23

and 32 are forcible arguments in favor of the causative influence of monocular defective vision in the production of squint.

6. Amblyopia is not a condition of alternating squint. Of the 12 cases in which either eye fixed, V. was equal in the two eyes with one exception, No. 44, where the difference can be accounted for by the higher optical defect. Its action, then, must be negative in the causation of alternating squint.

7. Amblyopia precedes the appearance of abnormal convergence and is not the result of nonuse. We have no means of determining with any degree of accuracy the inception of amblyopia, but that it is congenital, and hence antedates the squint, would seem reasonable, because:

(a) The duration of time after the squint was noticed until examination of the acuity of vision is, in the great majority of cases, too short to admit of the possibility of the development of the loss of vision from disuse. At no other time of life than in early childhood, and under no other conditions than those of functional internal squint, do we find examples of this kind of amblyopia. The retina may be shut off from participation in vision for many years by an opaque lens and retain acute sensibility. Other illustrations of this fact are not wanting. If squint causes amblyopia, amblyopia must always be associated with squint and should be cured after the axes are made parallel by operation. Neither of these assumptions is true.

(b) That binocular fixation secured after tenotomy is retained in a small proportion of cases, and in the great majority the result of operation is cosmetic only.

(c) Amblyopia does not follow, at least within several years, paralytic deviation of one eye. The image seen by the deflected eye is after a time consciously suppressed, but visual acuity does not degenerate into amblyopia.

8. The degree of H. does not determine the squinting eye. The table of cases shows the same error of refraction and in constant squint in 14; the higher defect in the fixing eye in 3, and lower H., but higher As., in the squinting eye in 4 cases.

9. The degree of H. does not determine amblyopia. A majority of cases shows practically the same degree in both eyes; a minority anisometropia; but similar differences are found in an equal number of cases which have never squinted and which have no amblyopia.

10. H. may be the determining cause of squint, since (a) all the cases with two exceptions were hypermetropic; (b) the relation of accommodation to convergence in H. encourages abnormal convergence; (c) convergent squint is sometimes cured during paralysis of accommodation and by wearing correcting lenses. There must, however, be other causes than H. in the majority of cases of squint, since—

I. H. is exceedingly common.

II. The proportion of cases of squint to cases of H. without squint does not exceed 1 to 50.

III. While squint is most common in H. of 2 D. to 4 D. (20 per cent), the ratio of cases of H. between 2 D. to 4 D. without squint to H. of other degrees is nearly 25 per cent.

IV. Internal squint is found in myopia.

11. H. As. must be considered equally with H. as a refractive cause of squint, and it may be, in some cases, the more important factor in determining the squinting eye. Astigmatism of 1 dioptré or over was present in the fixing eye in 21, in the deflected eye in 18 cases. The latter number should be modified by 5 cases in which, on account of amblyopia, it was not measured, but was probably present. In the 400 hypermetropic eyes without squint the number of eyes with As. of 1 D. or over was 49 = 12½ per cent. Hence As. is relatively more common in H. with squint than among those without squint. The axis of the correcting cylinder was vertical or within 10° in the deviating eye in 8, symmetrical in the two eyes or

within  $10^\circ$  in 6, and unsymmetrical in 4 cases. The remainder had As. of less than 1 D. or its degree was unknown. Among the cases of H. without squint 152 had As. in both eyes. Of these, 59 had axes vertical or within  $10^\circ$ , 33 had axes symmetrical or within  $10^\circ$ , and 50 had axes unsymmetrical. From these figures it is difficult to ascribe any importance to the direction of the axis of As. as a factor in the production of squint.

The second part of the proposition was true, in cases No. 7, As. 2 D. higher in the squinting eye; No. 23, 1 D. higher; No. 32, 1 D. higher; No. 41, 1.50 D. higher; No. 43, 2.50 D. higher; No. 50, .50 D. higher. In several cases where V. was decidedly bad and glasses made no improvement, it must be remembered that the As. was not recorded. If these eyes had been examined by the ophthalmometer it is probable that they would have been added to the list. On the other hand the fixing eye had the higher As. in Nos. 14, 24, and 47. It was practically the same in both eyes in Nos. 1, 2, 4, 9, 19, 27 (?), 35, 42, and 48. In the cases of alternating squint As. was 1 D. or more higher in only 1, and less than 1 D. in 11 cases (Nos. 17, 18, 20, 21, 25, 26, 28, 30, 39, 44, and 49).

12. A considerable difference in the degree of H. in the two eyes may not cause squint. Among the 200 cases of H. the total defect differed by 1 D. or more in 24, and in some (12) of these cases there was decided inferiority of V. in one eye.

13. Amblyopia determines which eye shall squint, and in its absence either eye fixes indifferently without regard to the degree of H., although it is unlikely that the difference in the ametropia exceeds 1 D.

A consideration of the preceding thirteen propositions leads logically to the conclusion that the generally accepted theory that functional internal squint depends upon hypermetropia must be greatly modified, and hence that our present method of treatment is unscientific and ineffective. We should look rather to the following conditions as likely to cause internal squint: Hyperphoria or hypertropia; congenital amblyopia; hypermetropia, heredity.

I have not discussed the complication which I believe to be most common in unilateral convergence, namely, a want of balance of the vertical muscles, since my data are too insignificant to be of service. My recent experience, however, leads me to believe that constant internal squint is almost uniformly associated with an upward or downward deviation, but whether as a cause or sequence I am not in a position to state. My statistics are incomplete also in that the results of treatment are not tabulated. This is not an accidental omission. Permanent results are difficult to obtain. If the patient is cured by one or more tenotomies he does not return. If he is not cured he consults another surgeon. The few cases of constant squint in which I can state the final result of tenotomies have shown little or no improvements, either in appearance or vision, and I candidly confess I had more failures than successes until I sought and found other causes than hypermetropia.

---

## SOME CONSIDERATIONS RESPECTING EXAMINATIONS AND TREATMENT IN HETEROPHORIA.

By GEORGE T. STEVENS, M.D., of New York.

Perhaps I may be pardoned in consideration of the subject assigned for this day's discussion, if I indulge in some satisfaction when I contrast the sentiments prevailing among oculists at the present time regarding that subject with those which prevailed only a few years since. At the meeting of the Ninth International Medical Congress, held in this city in 1887, just six years ago, I read before this section—the same gentleman presiding who now occupies the chair—a paper

with the title, "Some important problems respecting insufficiencies of the ocular muscles." Directly after the publication of this title in the medical journals I was violently criticised in some of the leading medical journals, not for the special views contained in that paper, for it had not yet appeared in print, but for the presumption and folly of suggesting that there were any problems regarding what were then known as insufficiencies of the ocular muscles. The public was emphatically informed that all the problems in this department of science had long ago been solved, and that there was nothing more for me to suggest nor for the profession to consider.

The writers undoubtedly voiced the prevailing sentiment of the profession at the time. Otherwise, had they expressed only their individual views, there would be no occasion for recurring to the incident here. To-day, six years later, this section of this great congress assigns one entire day to the study of the very problems which, six years ago, we were told had already reached a final solution. When, at the request of the president of this section, I consented to participate in this discussion, I was in doubt what I could best offer for your consideration. In reply to my appeals to the president to tell me what part of the subject he wished me to present, he gave me the whole field to discuss, but he did not give me more than one day in which to do it. At the last hour I have determined to speak, not of new things, but to direct your attention to some things of which I have already spoken, but placing them in a light which may possibly encourage some inquirer. If I shall be able to accomplish that, I shall be glad that I have chosen this course.

In the first place, I venture some words in regard to examinations for heterophoria. Perhaps the suggestions that I am to make are needless repetitions; yet I am led to the belief, by examining much of the current literature of the subject, that it may not be out of place to call attention to the fact that views from many points and much careful and logical thinking are essential elements in the making of these investigations. It is not, in the brief time allotted to me, possible to go into any details of examinations, but permit me to suggest an order and some important points which may be brought out by an orderly examination.

The facial expression of our patients will often give us strong hints of what we may expect to find. Indeed these expressions are so well marked in their relations to the condition of the ocular muscles that one who has had considerable observation and who is withal a close observer will rarely fail to make a general diagnosis of his case without the aid of his instruments. Of course, this is not a working diagnosis, but it is a valuable aid to that which is to follow, and often serves to direct the attention to slight inconsistencies in the instrumental examinations which otherwise might escape notice. A glance at the eyes themselves and at their movements prepares us, after we have learned what is necessary of their refractive condition, for the more exact examination.

First in order, after considering well the facial expressions and the movements, the phorometer is brought into use and its results recorded. If other instruments than the phorometer are employed for the purpose of indicating the manifest heterophoric tendencies, either by induced diplopia or by contrasting images, let me repeat what I have already said elsewhere, that no instrument of this class which is held near the eyes, or the correcting prism of which is brought close to the eyes, can be relied upon for such exact examinations as should be obtained if we are to make a critical study of our case. Some of the instruments which are in common use will give us false information to the extent of many degrees. The tendency to overcome a deviation of the images from the vertical or the horizontal lines is similar if not as strong as the instinct to unite images by overcoming prisms. If the phorometer is placed at the distance of from 4 to 6 inches in front of the eyes these adjustments, which are so naturally made, are either

entirely or in large measure neutralized. In whatever way we ascertain the phorometric measurements, we must bear in mind the important fact that we have arrived at only a single stage of the examination, and that other classes of facts must enter into the question of interpretation of the ocular adjustments. We must ascertain the abducting and the circumducting ability, and perhaps, also, the adducting ability. We are to observe the action of each eye when temporarily excluded from fixation and when it returns to fixation. If, assuming the standard abduction to be  $8^\circ$  at 20 feet, a standard adopted by myself many years ago, and which experience has shown to be a correct one, we find that it corresponds to the record of the phorometer, and if the circumduction right and left also corresponds to the indication of the phorometer, we may fairly assume that we have an uncomplicated case in which the reading of the phorometer may be taken as an index of the actual condition, so far as the kind of tendency is concerned. But if, as often happens, the records of the various tests; for example the phorometer, the abducting ability, the deviation in exclusion; are not in harmony, we are to search for the cause of this want of correspondence. For example, if by the phorometer we find esophoria  $2^\circ$  and abduction  $6^\circ$ , or even  $5^\circ$ , with equal circumduction and no hyperphoria, we arrive at the conclusion that we are dealing with a case of simple esophoria,  $2^\circ$  of which is now manifest. On the other hand, should we find esophoria  $2^\circ$  with abduction of  $10^\circ$ , or exophoria of  $2^\circ$  with abduction of  $6^\circ$ , we may at once conclude that we have a complicated case, even although there is no manifest hyperphoria, and one which must demand the most careful attention before any radical measure of treatment is adopted.

There are so many forms of these contradictory indications that I can only allude to them as a class as indications for the most careful study of the cases and as warnings that we must in no case assume that one class of testing tells us the whole truth. We should note the facial expression, test by the phorometer, try the ability to overcome prisms, examine carefully the rotating ability of each muscle and the action of one or other eye when excluded from fixation. These and often many other points are to constitute elements in our examination. And here let me add that if we are at the present stage of knowledge of this subject to publish our case the bare statement that the patient had an abduction of only  $5^\circ$  or that the phorometer showed a certain degree and form of heterophoria will not suffice for critical readers. Such readers must know all about that case. They have seen too many instances in which an abduction of  $12^\circ$  with an actual converging squint to accept such a bare statement as having any scientific value. Moreover, such a statement leaves in the mind of the critical reader the impression that the writer had not himself ascertained the remaining facts necessary to a just conclusion in regard to the nature of his case. A single word more regarding these examinations. Contrary to the general impression and contrary to my own teachings of many years ago, the correction of the refractive anomalies by glasses during an examination of this kind is not only in the vast majority of cases unnecessary, but positively detrimental, as the glasses themselves often lead to error, and their absence does not as a rule influence the muscular conditions.

And now that we have, in the few minutes, gone over the examinations in heterophoria, a subject which for its proper consideration would require the patient study of many months, let us as briefly sketch an outline of some of the methods for the management of the defects which we may have discovered. Let no one suppose that this sketch can be in any degree more than suggestive.

One of the first of the elements in the management of these cases is patience. The oculist who imagines that he can measure and correct his cases of heterophoria in an offhand manner has not reached an understanding of the first principles of the subject. A case which at first appears quite simple and easy to handle

may prove to be one which, for its best correction, may demand the exercise of great skill and of unwearied patience during many months. We can not know when we begin the treatment of a case of heterophoria the full meaning of the indications which we then discover. One who thinks that he has found an instrument which will reveal latent heterophoria is surely laboring under a misapprehension. As we go on in the treatment of these cases new difficulties may arise and new efforts may be demanded. This is no reason for not beginning the work and less for abandoning it before completion. I have sometimes illustrated these progressive difficulties by recalling the experience of one who climbs a mountain. He sees before him a height which appears to him the summit which is to reward him for his effort, but when he reaches it he sees before him another even higher than the one which he has surmounted. He ascends higher, and when at length he attains to the second height, the real summit is still far above him. Is he therefore to say there is no end of this, and one might climb indefinitely without finding the summit? There is a summit, and one may reach it if he has the needful strength and courage. I am sometimes asked by my colleagues if there is no end to the treatment of these cases. Does not the condition which has been apparently removed return? Must the treatment not continue as long as the patient will continue to submit to it? The heterophoric condition which has been in any measure properly corrected does not return, but that part of the original defect which was at one time latent may at a subsequent time become manifest. There is as surely a limit to this work as there is a final summit to the mountain, and when one reaches that limit he has an infinitely greater satisfaction than he who finally gazes upon the grand stretch of hills and plains and lakes from the great elevation which he has earned. Many who do not care to take the trouble to climb decline to accept the reports of those who do; and many an eminent man who has lingered about the foothills of this work is incredulous because he can not obtain the same grand view that has been described by someone who has gone beyond. An essential to success in this work must be a thorough knowledge of the principles governing the tensions of the muscles with which we work. Instruments can not know these principles. They are only to be learned by long and patient research on the part of the oculist. But what immediate steps are we to take for the relief of our patient with heterophoria? We may give him prisms. Will they help? Sometimes, and to a very limited extent. In the large majority of cases they will serve little purpose or perhaps produce decided annoyance. In the cases in which they afford relief that relief is in no sense the effectual degree of comfort and the absence of reflex trouble which may be expected from the more radical relief of abolishing the heterophoric condition. Then we may give to the muscles the gymnastic exercise which may be accomplished by the overcoming of prisms. That good may be accomplished in this way I have long ago demonstrated. The fact remains that the method is but tentative. The anomalous conditions remain, and the unpleasant symptoms will probably return. A vast experience with these two methods enables me, I believe, to speak of them with some degree of authority, and I do not hesitate to say that while they have much value to recommend them, and while no one can afford to overlook them, they fall far short of the more rational measures of actual adjustments by means of equalizing the tensions in such a way as to establish practical orthophoria. We may accomplish this by graduated tenotomies and tendon contractions. Are we then to operate for all cases of heterophoria? By no means. The surroundings of the patient, his methods of work, the importance of the case, and many such considerations must enter into the question of treatment. The best judgment of the experienced surgeon is here in demand. In most cases, however, in which important reflex disturbances are the result of heterophoria we shall find operative measures imperative.

How are we to operate? I must reply first in the negative. How are we not to operate? We are not to operate by the methods described in the text-books which I have seen. Indeed, if I may be permitted to diverge from our strict line of thought in a single sentence, I will add we should never for any condition of heterophoria, strabismus, or paralysis perform any tenotomy after the manner thus described. We should never operate in such a manner as to disable our muscle in its function of rotating the eye. We are told of tenotomies which are so far in excess as, after the relaxation, for example, of a single external rectus, to leave the patient with homonymous diplopia for some months. It is true that single vision may return and that even a condition of exophoria may succeed, but if the ability to rotate that eye well to the temple has been lost at the moment of the operation it will never return without a readjustment of its insertion. Let me impress this important fact upon the mind of everyone who operates for heterophoria, that whatever may happen in regard to phorometric indications, the rotation of an eye after tenotomy does not undergo any very important change and that we can not at the time of the operation disable this function in the expectation that the tendon will readjust itself. We should never attempt a complete and final correction on a single lateral muscle. If we have even a low degree of heterophoria we should proceed on the assumption that when we have finished the work we shall have relaxed the lateral muscle of one eye exactly, or as nearly exactly as we are able to determine, as much as we have that of the other. There is an important consideration too often overlooked in operations for hyperphoria, and especially for hypertropia, that the gaze of the great majority of our patients must be habitually directed downward. Hence a tenotomy of an inferior rectus is, as a rule, to be avoided, unless there are positive indications for selecting that muscle. Before any operation, even in well-defined cases, more than one, and usually many examinations should be made. Prismatic glasses, usually less than a nominal correction of the manifest heterophoria, should be given, and the patient should be charged to use them continuously during waking hours. From time to time, during the use of these glasses, examinations may indicate a greater degree of defects than was at first found and the prisms may be strengthened. The use of temporary prisms which are kept by the oculist, as suggested by me some years ago, has now become somewhat general. After a time, varying from a few days to a few weeks, we have either found such a degree of heterophoria as would be all that we might reasonably expect to relieve by a single operation without risking a restriction of the rotating power of the muscle to be operated upon, or there has been a halt in the further manifestation of heterophoria. We may now proceed with an operation. I have already more than once described this operation, but I will venture to do so again in order to introduce some details concerning which inquiries have often been made.

Let us suppose the operation to be done for esophoria, and that we have determined to do a graduated tenotomy of the right internal rectus. The speculum being in place, the patient directs both eyes well to the right. The surgeon takes with his fine forceps a minute fold of conjunctiva at the center of the insertion of the tendon. Drawing the little fold of conjunctiva slightly away from the eyeball, with the extreme points of his tenotomy scissors he snips the fold transversely so that an opening about one-half of a millimetre in extent is made through the membrane. Now the forceps, the points being closed, is pressed into the little opening and slightly backward, when the points are permitted to spring apart, after which they are again closed, this time holding a small fold of the tendon just behind the insertion. This little fold of tendon being put on the stretch, the fine-pointed scissors, by little snips, dissects the tendon from the eyeball between the layers of the capsule (which should remain intact) toward one border of the insertion. The sense of feeling of the fingers against the rings of the scissors will, in the hands

of one skilled in this operation, inform him of his approach to the border and warn him against its destruction. In extreme cases, like strabismus, the surgeon may determine to continue his section through the border, leaving uninjured as far as possible both the anterior and posterior lamellæ of the capsule as well as the expansion at each border to hold the muscle in its relation to the eye. Turning the scissors then in the direction of the other border, this portion is dissected with equal care. With as little delay as possible the patient is placed in the examination chair and the test by the phorometer and by prisms is made. It is safe in very moderate cases, by the first operation, to carry the correction to  $0^{\circ}$  and the abduction to  $10^{\circ}$  or  $11^{\circ}$ ; for at the moment there is likely to be a greater nervous relaxation than will be found an hour or more later, and it may be reasonably expected that within a few days there will still be a manifest esophoria sufficient, especially if the temporary prisms were again brought into use, to permit of a relaxation of the corresponding muscle of the left eye equal to that now being done on the right. Such an extent of relaxation may, however, be counter-indicated should it be found that the rotation, which should always be tested before the patient leaves the operating chair, is in danger of being unduly restricted.

Perhaps we find that esophoria is still manifest. The patient returns to the operating chair, when the surgeon, introducing the slender, blunt hook, feels for the point to which the section has been made either above or below. He soon finds, if he is expert, whether the section has been carried far enough in that particular direction; and, if so, he searches at the other extremity. If he now finds room for carrying the section further, he, using the slender hook as a guide, increases the effect of the tenotomy by carefully executed snips of the scissors, and after an examination this process may be renewed if required. If by chance we find that we have erred in judgment and have gained an exophoria with abduction exceeding  $11^{\circ}$ , we must at once introduce at the exact center of the free end of the tendon a very delicate suture, carrying it through the cut edge of the conjunctiva at the corneal side. There is an occasional exception to this rule, in which, if we permit the patient to wait for an hour or less, the exophoria and excessive abduction disappear spontaneously. We make this suture to include as little as possible of either tissue, and then draw it with great care until we have overcome the exophoria, as shown by the phorometer, when the knot may be made fast. This process, although sometimes demanded in the practice of the most skillful, is always unfortunate. Those who tell us that we should cut the tendon across and then introduce the suture are laboring under a serious error. Should it be found on the following day that the result is not what could be desired, the suture may be renewed, or by removal an increased effect of the original operation may be obtained.

There are conditions which render it almost imperative in a certain small proportion of cases to make adjustments in lateral tendencies which, although not more than nominally correct at the time of making, are such that the experienced surgeon feels almost sure that when he is better able to adjust for a supposed hyperphoric condition will at length prove overcorrections. Such overcorrections, when they become manifest, must be restored to equilibrium. Now, it should be an axiom, a rule never to be forgotten, that we have no right in any case to weaken a muscle because we or someone else has weakened the opponent of that muscle. For example, if, as the result of a tenotomy of the internus of one eye, we have as a result an exophoria of even as little as a single degree, it is inexcusable to cut the externus in order to relax that muscle equally with the excess of relaxation of the other.

Let me repeat we are not to correct an overcorrection by a new tenotomy. In all such overcorrections we should resort to tendon shortening or tendon advancement of that muscle which has been too freely relaxed. If the original tenotomy

has been done in the manner I have just described there will be little difficulty in performing a correction which shall leave no cicatricial bands to interfere with the freest action of the muscle.

We begin in this operation, as in that for tenotomy, by making a transverse slit of one-half millimetre in extent over the point of insertion of the tendon. Then lifting the border toward the cornea by the fine forceps, a little pocket is made by the points of the scissors, extending under the conjunctiva, more or less toward the cornea in proportion to the greater or less effect which we propose to induce. The pocket having been made, the forceps seize the central portion of the tendon, and it is dissected from the eyeball entirely or partially, as the case may be. If it is entirely dissected, then by means of the scissors points acting as a probe, or by means of the lance probe, the tendon should be absolutely freed from any attachment to the surrounding tissues. The fine tendon crochet now catches it at the center and a little behind the section and draws it forward, or if the hook proves to be ineffectual to hold it during the next stages of the operation the fine fixation forceps with catch may be used. The tendon is drawn forward through the little conjunctival opening, when one of the needles from a thread of silk armed at each end with a needle is passed through the central part from one-half to a full millimetre, or even more, behind the cut extremity. Bringing the needle forward until the two extremities of this thread are about equal in length, an assistant carries the lance probe into the pocket already made, and one of the needles, passing by the side of this probe, which acts as a guide, is made to penetrate the conjunctiva at the extreme end of the pocket and the thread is drawn through. The other needle and its thread are managed in like manner, the second needle penetrating a little to one side of the first in order to allow, between the two threads, a little bridge of tissue. Now, the assistant holding the conjunctiva at the border of the wound by means of fine forceps, the surgeon draws upon the ends of the thread, forcing the cut end of the tendon into the little pocket, and when he has thus advanced it to his satisfaction he fastens the threads by tying them across the little bridge. No cover and no especial care are required beyond that needed for perfect cleanliness, and on the third or fourth day the suture may be removed. The greatest danger in these cases arises from the use by the patient of a soiled handkerchief with which he rubs the eye. Against this danger the strictest injunctions are to be enforced. This operation, with such modifications as may be required, I have performed during the past five or six years in many hundred cases, and it has been witnessed by some scores of my colleagues.

---

#### DISCUSSION.

Dr. Burnett, of Washington, D. C., said that in view of what had already been said in this discussion it did not seem necessary to insist upon the importance of muscular errors in the production of symptoms referable to the eyes, head, and even remote localities as due to these defects. Probably no one present ever doubted the existence of grave muscular errors and the necessity for their correction. The problems before us, then, would seem to be the best and readiest methods for their detection; the muscle or muscles involved, their extent of involvement, and the treatment necessary for relief. And the further we go into the study of the question the more complicated it becomes in all these particulars. Formerly the dot and line test of Graefe was considered all that was necessary for determining muscular insufficiencies, but now no one of a half dozen or more methods is deemed infallible; and in some cases all seem to fail, and it is only by the exercise of great patience that the absolute power of the muscles

involved can be determined, if at all. I would dwell more particularly upon the difficulties in determining hyperphoria. As we know from the teachings of our physiologists the interni and externi move the visual axis in what is approximately a horizontal plane. Their simple action gives no vertical or rotary motion to the eyeball. So the problem in exophoria and esophoria, pure and simple, is a comparatively easy one. I would call attention to the remark made by Dr. Stevens that a complete tenotomy of the interni, for example, might, by a faulty union, give rise to a pathological rotation of the eye. This he did not think was liable to happen if the muscle was allowed to go free, as when it was sutured. But if this is to be feared so much as the result of the operation, how much more should we consider its possibility as a primary condition. We must remember that the upward and downward movement of the eyes is an exceedingly complicated one and is not made by one set of muscles. The superior and inferior recti and the obliques which make these movements have also a lateral and rotary movement each, and as the recti and obliques are astigmatic in this portion of their action we should in every case of hyperphoria be able to put our finger on the faulty muscle. If we can not, our therapeutics, whatever it may be, must be, in a measure, blind. So far as I am aware, no effort has yet been made to detect and measure this error of rotation in hyperphoria, and yet it must exist in some degree in every case, and it will be different according as the obliques or recti are involved. There is every reason for supposing that the effort on the part of the eye to overcome this faulty rotation and to bring the inclined line of one eye into the plane of the straight line of the other eye lies at the bottom of the trouble in hyperphoria quite as much as the vertical deviation. And it probably also accounts in no small degree for the unsatisfactoriness of the vertical diplopia which we find mentioned not infrequently. It is fortunate, however, that as far as surgical therapeutics goes, there is this correlation in the action of the recti and obliques, for it will enable us when an error is clearly diagnosticated to correct it by an operation on the associated rectus. My friend, Dr. Savage, is the only one who seems to be working on these lines, and I hope his sanguine expectations may be realized. Two years ago I reported to the Ophthalmological Society my experience in tenotomies, and from the favorable opinions there expressed I have had, from my subsequent experience, no reason to recede.

Dr. Gould, of Philadelphia, said that according to Dr. Burnett, who undoubtedly represented the general consensus of feeling of ophthalmologists, the well-recognized treatment in decided cases of heterophoria was that of tenotomy, either partial or complete, according to the circumstances. This to the speaker seemed to be a true tenotomomania, and one illustration of the general surgical debauch of these days, which has also been so well illustrated in gynecology. It should be remembered that surgery is not medicine, that it is the despair of medicine, and a dernier ressort. The true physician only proceeds to surgery when medicine is no longer able to bring relief. The speaker believed that in a very few years from the present time there will be little or no tetonomy in cases of insufficiency of the extraocular muscles. He protested that the whole muscle question is not a muscle question at all; that the origin of the trouble is not in any peripheral organic defect, but that it is almost entirely of central origin or nature, and that it is functional and not organic. A large number of cases of course are to be set aside as due to general disease and abnormal conditions existing in other parts of the system. If this is the true view, the cure must therefore be a cure, not of the peripheral organs, which are not at fault, but of the nerve centers controlling the extraocular muscles, because in uncomplicated cases the disease is a disease, if it may be so called, of the nerve centers and not of the muscles themselves. The essence of the diagnosis consists in the relation between adduction and abduction. Leaving out cases of heterophoria, if we have an adduction of  $25^{\circ}$

or  $35^{\circ}$  and an abduction of from  $4^{\circ}$  to  $8^{\circ}$ , there is certainly no insufficiency and no demand for interference with the muscles of the eye. The secret of the whole matter is to reinstate such a proper relation between adduction and abduction. Every case of heterophoria not traceable to general disease, malnutrition, ametropia, etc., the speaker believed to be curable without any operative interference, by a course of gymnastic exercises with the object of developing the strength of the innervational centers. In all other cases of incoördination of the muscles of the body we do not cut a strong muscle or group of muscles in order to strengthen a weak muscle or group of muscles, but instead of that we endeavor to develop the strength of the weak muscles. And so in heterophoria, the true therapeutic measure is to develop the weak muscles. The speaker had discovered by experiment a method of developing these weak muscles, which he believed might be of service, and which had proved very successful in his hands during the last year. In all cases of insufficiency that had not proceeded so far as strabismus, there is during convergence singleness of the images in vision and an increased ability or strength of the coördinating muscles brought into play. The problem then simply consists in carrying this power, developed at the near point of vision, to the far point; in other words, of so developing the nerve centers that the stimulus of converging power shall be enlarged until the same power exists in the distant vision. To illustrate the method the speaker cited a number of cases, in which there was exophoria at 20 feet of from  $5^{\circ}$  to  $15^{\circ}$ , and adducting power of from  $10^{\circ}$  to  $20^{\circ}$  only, and an abducting power somewhat in excess of that needed. By placing prisms before the eyes, base out, twice as powerful as the patient could fuse at 20 feet, and beginning with the stimulus of convergence at the near point, the object could be very soon carried beyond the near point without producing diplopia, and in a very brief period of time the internal recti muscles had gained their normal strength, the adducting power had increased to  $30^{\circ}$  or  $35^{\circ}$ , and the reflex symptoms had entirely disappeared. A number of cases of this kind were cited, in which the cure had been brought about within a few weeks in young people, and in the more neurasthenic or older patients if the insufficiency had not been made to entirely disappear there was a great improvement in this respect, which was first demonstrated by the disappearance of the reflex symptoms. As the weak muscles regain their power stronger prisms may be used, and there is a perfect coördination and proper relation between adduction and abduction. The speaker especially referred to a case in which there was  $18^{\circ}$  of esophoria. The patient was operated upon, the tendons of both internal recti being completely severed, producing temporarily slight exophoria. To the astonishment of the surgeon the original condition was reinstated within ten days, and the patient's original  $18^{\circ}$  of esophoria had completely returned. If such a result as this could arise (and the speaker contended that there was a tremendously large element of doubt as regards the results of operations upon the muscles of the eyes) what, then, could be said as regards the infinitesimal delicacy and minutiae of operations when surgeons speak of correcting half a degree, or one or two or three degrees of heterophoria of any kind? Such a result also conclusively proved that it was not a case of peripheral lesion, but that the trouble lay in the central nervous system, a theory moreover which was proved by the subsequent history of this patient, who refused to submit to further operation, and upon whom the principle of gymnastic exercises of the weak muscles, according to the plan described, was undertaken. Although the  $18^{\circ}$  of esophoria had remained permanent for some months after the first operations, within a week or two after these gymnastic exercises had been undertaken the patient's esophoria had been reduced to 12 degrees, with a cessation of many of the reflex symptoms. The case is still under treatment and progressing favorably.

It would seem, therefore, that as conservative and wise physicians we should not longer indulge in this glamor of surgical procedure, but with more conserv-

atism that we should seek to remedy defects by physiological and medical methods rather than by surgical methods. The success that in the speaker's practice had attended this plan during the last eight months had been so remarkable as to convince him that the method of carrying the convergence stimulus into the distant vision and the developing of the weak nerve centers was the true and rational method of procedure in these cases.

Dr. Savage said: I am exceedingly sorry that Dr. Stevens is not here, since it is my purpose to controvert some of the thoughts set forth by him in his discussion this morning. I agree with him in many of the views he holds, but I consider that he is wrong in his teaching as to some very important practical points. I agree with the Doctor that associated with muscle errors and depending on them there are peculiar facial expressions. I wish I was as able to interpret these as he is. But he stated that sometimes the facial expression clearly indicated the existence of a certain muscle error which is not at once shown by the tests at our command. In connection with that statement he did not tell us his method of dealing with these cases. We may reasonably infer from what he said further on in his discussion that the facial expression having indicated a hyperphoria, but not finding it with the phorometer it was found by means of prisms in position of rest for the suspected weak muscles, of action for the supposed strong muscles. Continuing this for a few days the latent error begins to be manifest, and the tests begin to harmonize with the facial expression. I believe the facial expression may sometimes be misleading, and that, as an index to a muscle error, it can be proven false or true by our muscle tests. I believe further that means should never be resorted to, under any circumstances, for making manifest any supposed lateral error. If we have a "hint" that we are about to deal with a left hyperphoria and a right cataphoria, it is clear to my mind that we should direct our efforts toward curing the slight manifest error, rather than add to it by bringing out a latent error. If a prism be placed base down before the left eye and another prism base up before the right eye, in the supposed case, the strong muscles will be made stronger and the weak muscles weaker, in comparison. This work could be carried on, up to a certain point, and thus a greater or less quantity of a supposed latent error may be manifest. How much better it would be to reverse the order and make it possible for the error already manifest to become latent by being cured. Place the prisms in position to strengthen the weak muscles, regulate the exercise as to intensity and time, and they will grow strong. The only object we could have in view in increasing the hyperphoria is that a sufficient quantity may be shown to justify operative interference. This seems to me to be a very round-about way to effect a muscle balance; and I believe it to be a very incorrect method. If one believes the operations alone can correct muscle errors, then he must of necessity often resort to the work of making manifest much that is latent, so that an operation might be indicated.

I must dissent from another thought which Dr. Stevens emphasized this morning. He plainly stated that he did not believe the accommodation has anything to do in the way of causing or curing any form of muscle error. In this I believe him to be wrong, so far as the latent muscles are concerned. As evidence, I want to introduce one of his own cases. A few years ago in one of his publications he gave the history of a patient who, when a little girl, had an internal squint; later in life there developed a slight deviation outward, but now, on instilling atropine, she suddenly developed her old internal squint. He published a picture of this patient, representing her as a little girl with an internal squint; also a picture representing her as a woman approaching middle life, with eyes comparatively straight; and still another picture, showing the same woman, at the same age, under the influence of atropine, which had excited a high degree of internal strabismus. He states that the squint disappeared when the effect of the

atropine passed away. Having had patients like this one, I am sure I do not err in the statement that she was hypermetropic, though the Doctor's report did not give her refraction. Early in life, where she had full ciliary power, the activity of the centers controlling the ciliary muscles excited a tendency to activity in the centers controlling the converging muscles that would not be restrained by the guiding sensation, and one eye turned in. Later on the ciliary muscles having lost much of their power, the centers controlling these became less active and correspondingly there was less excitation of the converging centers, so that the guiding sensation again assumed control of the internal recti, the squint disappearing simultaneously. Atropine suspended what ciliary power remained and, as a consequence, very imperfect images were formed on the retinae. The guiding sensation, not being satisfied with these images, called on the accommodative centers for help. In response to the call, these centers generated an impulse and sent it out to the ciliary muscles, but they were not aroused. Another complaint went forth from the guiding sensation, more urgent than before, and by it a greater degree of activity was excited in the accommodative centers; but every impulse, though increased in intensity, found the ciliary muscle unresponsive. In this manner the calls and responses were kept up from hour to hour. This activity of the accommodative centers was attended by a corresponding tendency to activity on the part of the converging centers, which tendency having thrown off the restraining influence of the guiding sensation, became unrestrained action, developing the internal squint. As demands on the accommodative centers ceased, the unusual excitation of the converging centers passed away, and with it the muscles again became obedient to the restraining commands of the guiding sensation, and the squint was no more.

I have had numbers of just such cases, and have often amused myself by satisfying the guiding sensation with sharp images by placing correctly centered lenses before the eyes, when, as if by magic, the squint would disappear, only to appear again the moment the glasses were raised. For this there can be but one explanation; the sharp images (made so by the lenses) satisfied the guiding sensation, which instantly ceased its calls on the centers of accommodation, and as a consequence both the centers of accommodation and convergence became quiet. We need no stronger evidence that the centers of accommodation have the power of changing the "balance" between the external and internal recti-muscles. If this relationship can develop a squint, certainly it can cause an esophoria, which is a "latent" squint. If glasses, properly centered, can cause a squint to vanish, is it incredible that glasses can cure an esophoria which depends for its existence on an uncorrected hypermetropia? In a recent publication I have termed this a pseudo-esophoria and distinguish it from intrinsic esophoria, which can not be cured by convex lenses. The two may be associated in a case of uncorrected hypermetropia, while the intrinsic form can only exist in cases of emmetropia and myopia. In volume 2, No. 11 of the *Ophthalmic Record*, this whole subject is dealt with at length. While glasses have the power, when properly adjusted and properly centered, to cure some pseudo-muscle errors, they have no power at all over intrinsic heterophoric condition. As pseudo errors may be classed those muscle anomalies dependent on decentration of the muscles, and these can be cured, and ought to be cured, only by prisms in position of rest, or, what is the same thing, by decentered lenses.

Since focal corrections can do nothing for the cure of intrinsic muscle errors, and since prisms in position of rest should never be prescribed for a correction of these errors, the question naturally arises, "What shall we do for their relief?" There are two plans of treatment, each appropriate in its place: Rhythmic exercise for developing the weak muscles; operations, partial tenotomies for weakening the strong muscles, and shortenings for giving greater power to the weak muscles.

The indications for the one or the other are clear to my mind, and my practice is governed by these indications. When there is exophoria of any quantity in the near but none in the far, the case does not admit of operation. The plan of rhythmic exercise which I have introduced will cure the exophoria in the near and allow orthophoria for distance to remain. An operation in such a case would give as much esophoria in the distance as it cures exophoria in the near; therefore it should not be thought of. Again, when there is esophoria for distance and orthophoria in the near, the error for distance can be cured by gymnastic exercise allowing the orthophoria in the near to remain. An operation would give as much exophoria in the near as it cures esophoria in the far; therefore it should not be done. A hyperphoria of less than  $1\frac{1}{2}$  degrees should be cured by gymnastic exercise. When there is exophoria both in the far and near, that for distance should be corrected by a partial tenotomy of one or both external recti, and later the exophoria remaining in the near should be cured by developing the internal recti by exercise. When there is esophoria both in the near and the far, that in the near should be relieved by operating on one or both internal recti, and the esophoria remaining in the distance should be cured by developing the external recti by exercise. When there is hyperphoria of more than  $1\frac{1}{2}$  degrees an operation on the tendon of the superior rectus should be done to effect a part of its cure. Rather than overcorrect, it is far better to fall short of a full correction, and cure the remaining part by developing the weak muscles by rhythmic exercise. No muscle should be operated on more than once. If an exophoria for distance can not be corrected by a partial division of the tendon of each external rectus, the balance should be accomplished by shortening one or both internal recti. Reversing the order, the same course should be pursued in very high grades of esophoria.

If in a high grade of hyperphoria there should be more than  $1\frac{1}{2}$  degrees of the error after a partial tenotomy has been done on the strong superior rectus, a similar operation should be done on the strong inferior rectus of the fellow eye. Shortening or advancing a superior or inferior rectus will not often be necessary; I have never seen a case requiring it.

When I am about to operate I decide beforehand what I want to accomplish, and do what I undertake without resorting to tests during the operation. I always aim in exophoria and esophoria to divide the effect between the corresponding muscles of the two eyes, but as a rule do not operate on the second muscle within four weeks. Not infrequently I find that my first operation has accomplished all I desired. Never has the first, and in only two instances has the second, operation accomplished more than I wanted, and my operations run up into the thousands. Before devising the rhythmic exercise treatment I did desire, not being able to do better, to give by my operation some esophoria for distance in relieving some of the exophoria in the near, and *vice versa*. With Dr. Gould, I agree that unnecessary operations have been done on the ocular muscles, and that bad results have followed, all of which is to be regretted. These errors can be, and should be, avoided. The fact that bad results have been seen should not and, I dare say, will not drive all thinking men from acting on sound principles. These operations can not be called surgical debauchery when carefully and skillfully done. There is nothing under the sun more sure than that there are intrinsic errors of the ocular muscles, errors the nature of which may be clearly understood, errors that can not be cured by any and all medical means at our command, or that may be at our command in the future. Even glasses, purely surgical appliances, can not alter the true nature of inherent muscle troubles. Glasses and medicines, I grant, may so act on the nervous system as to make these errors more tolerable, at least for a time. But the errors are there still in spite of all these means. As they can be made more tolerable by improved systemic conditions, they can, on the contrary, be rendered less tolerable by sys-

temic derangements and extraneous causes that disturb mental equilibrium. The fact remains, and will always remain, that intrinsic muscle errors; errors due to hyperdevelopment of the too powerful muscles, or to a more favorable attachment of these muscles to the globe, or to their having inherently and persistently a too abundant nerve supply; can be cured by any one of two means, both surgical in their nature; first, operation on the strong muscles; second, development of the weak muscles by proper gymnastic exercise. The indications for the one or the other of these, or for both combined, are clear in most cases. Surgery is not the despair of medicine, but medicine's hope. As to ocular troubles, medicine does not appeal to surgery in vain. The two forms of ocular surgery applicable to the ocular muscles will go locked hand in hand down the ages, each to do its own proper work and ever ready to call on the other for aid in time of need. No, the days of well-done partial tenotomies are not over, nor will they end with the hundredth generation of oculists to follow us.

Dr. Risley remarked that heterophorias declared themselves in the facial expression of his patients. He was sure that those who devote themselves to the study of this complicated and intricate subject must sooner or later exhibit the results in their anxious and haggard faces. The gentleman who had preceded him had been preserved from the gray hairs, so numerous in the section, by the buoyant faith in his methods. For his part, the gloved hand of conservatism was controlling more and more his management of the errors of muscular balance. While the careful study of the relation between convergence and accommodation was of great importance, no study of these cases was complete which did not take for its starting point the etiology. The proper dynamic relation between the interni and externi was as 3 to 1 determined at 6 m. This was based upon the careful study of a very large group of corrected eyes in which no muscular anomaly existed, and asthenopia was absent. When this relation does not obtain errors of muscular balance may be assured. The etiology of such disturbance is important and should control the management of the case. Some cases are unquestionably congenital and possibly due to errors of development; in others, seen in adult life, the esophoria is a residuum of periodical converging.

*Strabismus in childhood.*—This could in some cases be demonstrated by the study of photographs taken in childhood. Foreign irritations were not infrequently the cause of trouble in ocular muscles. He related the history of a case in which a pessary had removed the heterophoria, which had seemed to require tenotomy. The ocular muscles were subject to disturbance by general diathesis as are the other muscles of the body, rheumatism, gout, etc., and a heterophoria might, therefore, be due to a rheumatism of one of the muscles or the residuum of a palsy. It was probable that a muscle once the subject of a palsy, whether peripheral or central, never entirely recovered its original efficiency.

Disturbance in ocular balance was often the initial symptom in babes, or disuse at the origin of one or more of the nerves supplying the ocular muscles, and error was very liable to creep in at this point. He could not agree with the dictation of Dr. Stevens regarding the refractive errors in relation to muscular trouble, since, in his judgment, the two were inseparable in that group of cures of peripheral origin.

Dr. Baker, of Cleveland, said that he thought Dr. Gould would have little occasion to regret his strong condemnation of the promiscuous snipping and cutting of the tendons of the ocular muscles now indulged in by certain ophthalmic surgeons. He said that for many years we have been endeavoring to so perfect our means of correcting errors of refraction as to be able to cure cases of strabismus without resorting to tenotomies, and now that we had about succeeded in curing most of these cases without operative interference in which there is a positive rational indication for operation. These fellows come along and tell us that we must

operate in every case where there is the slightest deviation. He believed division of the tendons in most cases to be unnecessary, and he thought partial tenotomies unscientific and unsuccessful, that a partial tenotomy eventually shortened instead of elongated the tendons, and that when a tenotomy was performed a complete division of the muscle should be made and controlled by a suture, if necessary.

Dr. Woods, of Baltimore, said: The entire discussion seems to point to the fact that the oculist in treating heterophoria must remember that he is a doctor; that he is investigating a condition sometimes troublesome, sometimes not; sometimes intrinsic, sometimes secondary; that the primary cause is sometimes in the eye, sometimes elsewhere. As Dr. Burnett has said, we are to look into the etiology. If we are not capable ourselves of meeting the remote conditions, we should seek help rather than do a doubtful operation. Dr. Risley has, I think, given, as nearly as they can be given just now, the correct principles. I have had a case similar to the one he mentioned; a young woman employed in a store, whose head and eyes pained almost constantly. Correction of myopic astigmatism against the rule failed to relieve her; so did prismatic correction of an exophoria. An operation to remove a uterine defect and some menstrual disturbance cured her, eyes and all. I have a patient, a lady, who does a great deal of eye work, and who for several years has obtained relief from headaches by wearing cylinders; yet she has a hyperphoria of  $2\frac{1}{2}^{\circ}$ . Surgical interference in this case would have been bad. In the first, it could not have reached the real cause; in the second, there could be no reason for correcting a "tendency" which was doing no harm. On the other hand, when the heterophoria is intrinsic, and really causing the disturbance, results are brilliant. The gratitude of patients thus relieved, so well presented by Dr. Risley, shows what great good can be done. The question is to determine what cases need operation.

There are a few points in the papers of the morning, and remarks made at this session, about which I should like to say a word. Dr. Stevens's advice for journal writers to give all the details of a case in reporting, and not simply say "such and such an error of so many degrees," should be followed. Such reports of cases, in the present state of heterophoria, are useless. I wish very much Dr. Stevens was here this afternoon to explain why correcting glasses should not be worn during the muscular examination, as he stated this morning. This contradicts all his former teachings, as far as I know, and opposes all the recognized principles of refraction. According to my way of thinking, an examination of the muscles without refraction correction would be valueless. Dr. Savage has said he "would not develop the interni out of a near exophoria," and "would correct the esophoria up to its amount at the near." If the principles I advocated in my paper this morning are correct the former might be a normal condition, and it might indicate either hypersthenic or weak ciliary muscle. The clinical significance of the esophoria at the near would depend entirely on what had been found at 20 feet. If more esophoria, how much more? I do not believe that any valuable information about the intrinsic strength of the recti muscles is to be gotten from the near equilibrium. This is gotten at 20, and the near test is made for an entirely different purpose. It seems to me Dr. Risley has underestimated the normal proposition of adduction to abduction. I am inclined to think that it is more frequently 5 or 6 to 1 than 3 to 1. The cross shown by Dr. Zeigler this morning for the near test seems to me too large to bring out exact accommodation. The smaller the object, the better. Again, it should be mounted on some sort of a rod which would keep it at a fixed and definite distance from the eye.

Dr. Zeigler said: I hereby agree with what Dr. Woods has said in regard to the interrelation of the distance and near test. This is illustrated by an anomalous case I related in which the esophoria for near was  $6^{\circ}$ , while for far it was only  $2^{\circ}$ . I was compelled to bring the eye to orthophoria for near, with the accompanying transfer to exophoria of  $4^{\circ}$  for distance, before I could secure comfort in the near

work. I do not find that the record of muscular power bears any important relation to either operative or prismatic correction of heterophoria, although we should have an accurate knowledge of it for other purposes. Dr. Stevens, I believe, said that he did not believe in the statement that the ciliary muscle may disturb the condition of the extrinsic muscle of the eyeball. I think we have all seen temporary heterophoria from ciliary spasm, and per contra ciliary spasm from functional muscular errors. The relation between accommodation and convergence is certainly an intimate one. Relying on this fact, I always adjust the proper constant correction in my trial frame, and place in front of patients' eyes in both operative and nonoperative cases. In fact, a test with and without the refractive correction will show different results, just as a test under mydriatic is only a matter of interest, and not to be relied on, because the accommodation is suspended. Dr. Stevens referred to a case in which I overcorrected the exophoria  $5^{\circ}$ . It was a case of esophoria of  $20^{\circ}$  reduced to orthophoria by the total tenotomy, which had receded to  $10^{\circ}$  base out. A complete tenotomy was made on the internal rectus of the other eye, overcorrecting  $10^{\circ}$ , and again it slid back, coming to orthophoria or  $1^{\circ}$  beyond. I think the history of this and similar cases justified me in doing as I did; and five months of comfort for the patient goes to prove the same. In regard to advancement I prefer the capsular advancement in heterophoria and the muscular advancement in heterotropia or squint. To get the best effect in the latter cases the adhesion should not be loosened but drawn up with the muscle. In regard to covering the eye: I am a firm believer in light dressings. In cataract extraction and other operations requiring corneal incision I use two strips of plaster in the shape of a cross, one from the upper to lower lid. But in these walking cases exposed to the weather and having considerable bloody ooze I prefer a light compress and Lilbright patch for the first day and night. I have seen one case in which an exposed eye was lost from diphtheritic infection, and I have had one case in my own practice where, in facing a cold wind on the second day, the eye became inflamed and presented a most beautiful picture of culture of *staphylococcus pyogenes aureus*. While no harm came to this patient I still consider it good judgment to adhere to a light dressing in a certain portion of my cases. I never have used them in every case. In regard to failure to correct cases of internal squint I think we frequently overlook the capsular adhesions which, when cut, may allow the eye to turn from 5 to 10 degrees. They particularly amount to a shortening of the muscle. I think we all use muscular gymnastics with great relief in some cases, and none in others. I agree with Dr. Risley in regard to uterine irritations. I remember a very hopeless case of heterophoria in a woman whom I referred to a gynecologist, who was wholly relieved by an ovarian operation. Replying to Dr. Woods, I would say that I have generally used a smaller cross for the near test, but the engraver has made an error in making this larger cross. The card I presented is the first proof. I do not, however, hold the near-test object at a single point, but take the range.

#### TREATMENT OF OPACITIES OF THE VITREOUS HUMOR WITH PILOCARPINE HYPODERMATICALLY ADMINISTERED

By Dr. T. J. TYNER, of Austia, Tex.

I will not take up your time by giving the anatomy and physiology of the "corpus vitreum" further than to say that it is without either blood, nerve, or lymphatic circulation. This opinion is, I believe, now accepted by most, if not all, recent authorities and my clinical experience is in accord with it. It would be a pleasure to give a satisfactory theory as to how these opacities clear up under the influence of this drug (pilocarpine). That it differs from all other drugs in its physiological action there is no doubt, and that it is a specific in this

disease, or rather condition, I have demonstrated, at least to my own satisfaction. That there is ever a primary inflammation of the vitreous I can not believe. However ingenious some writers have been in the opposite theory, for the most part, in their conclusions, they have been forced to regard these opacities as the result of some previous inflammation in the uvea. It is most generally believed that a cure is impossible, except in recent cases. This is only in part true, and true only for the reason that the previous inflammation in the adjacent tissues, especially the retina, and from which these opacities or exudates enter, has been such as to permanently affect vision. This is clearly proven by the disappearance of the opacities, without corresponding improvement of vision; and when the media become sufficiently clear to see the fundus the ravages of a preceding choroiditis or retinitis is revealed. The iris, especially in old persons, is frequently atheromatous, the pupil responding to atropine only in part. Such cases are rarely met with, except where they are of long standing, and generally in elderly persons. I treated a gentleman 72 years of age whose vision began to fail six years previously; the media became perfectly clear and vision improved very much, as much as was possible, so far as the vitreous was concerned, but with the ophthalmoscope the scars of a preceding inflammation of both the choroid and retina were made manifest. However, such cases do not detract from the efficacy of pilocarpine in rendering the vitreous clear of opacities. As to how it does it, as before stated, we can not say. That it is not by absorption is almost certain, for so far as is known the vitreous is devoid of absorbents. I will, however, venture the hypothesis that through the lymph channels endosmosis is probable, and that the opacities are disrupted and resolution takes place.

I could not do better than refer you to a paper read at this meeting by Dr. J. W. McLaughlin on "The philosophy of drug action." However much we would like to know the process by which a thing is accomplished, yet the practical fact that we know the agency by which it can be done should be sufficiently satisfying, and my clinical experience warrants me in saying that the hypodermic injections of pilocarpine is a specific in opacities of the vitreous humor. In support of this statement, since the beginning of 1887 I have treated about 31 cases in which there was not one that failed either to fully recover or to be greatly improved. Those only improved were the cases already referred to, in which a precedent destructive inflammation in the uvea had existed. It will not be amiss to state here that in one case in which the opacities had appeared only ten or twelve days before,  $V = \frac{20}{40}$ , at the end of the first week of treatment it fell to  $\frac{20}{100}$ , showing the inflammation in the uvea to be at its height, but thirty days later  $V = \frac{20}{20}$ . The oldest case treated was 91 years of age; the youngest, 18. The age most susceptible is about 50 or say between 45 and 55. The case of longest standing was eight years, the shortest twelve days; but for the most part between one and two years when the patients present themselves for treatment. Sex, 27 males; 4 females. (*Noteworthy.*) Of the 31 cases, 4 were colored, 1 mulatto. In administering the drug, I proceed with extreme caution, beginning with about the one-sixteenth of a grain twice daily, increasing the dose as rapidly as possible until the full physiological effect is reached, then continue. Generally though, after this, only once daily. A larger dose can be given at the patient's home and with much more comfort than at the office. The reason is obvious. As a rule, the greater the effect of the drug the more rapid the improvement.

#### DISCUSSION.

In discussing Dr. Tyner's paper, Dr. Chisolm said that he had for many years used pilocarpine by hyperdermic injection for the relief of recent cloudings of the vitreous and with excellent results. He usually commences with a really stronger

dose than Dr. Tyner ends with. He injects one-fourth grain and usually obtains free sweating in a few minutes, with salivation and at times emesis. He had seen no bad effects from these doses. The more prompt and excessive the skin action the more prompt the clearing of the clouding.

### ORBITAL TUMORS.

By WALTER B. JOHNSON, M. D., of Paterson, N. J.

Exophthalmus, from any cause, is unsightly, and when it is produced by the presence of some variety of orbital tumor is always to be regarded as an extremely grave condition, for the presence of a growth behind or within the eyeball is serious, and may, even if a suitable case for operation, result in loss of the eye if, as in many cases, it does not terminate in the death of the patient. The histories of the cases of the tumors of the orbital cavity here presented, which differed in their composition and had their foci of development in various localities, are reported, without any special effort at classification, for the purpose of placing them on record, and for the consideration of the interesting features always presented in the study of cases of so grave a character.

Protrusion of the eyeball when presented, as a symptom, for examination should be carefully considered from every standpoint, and the diagnosis and treatment of the possible condition only suggested after deliberate inquiry and investigation and a thorough study of the probable prognosis and requisite medicinal or operative treatment. The important factors which present themselves for consideration, are: The presence of an orbital tumor, and the character of the growth whether benign or malignant. The previous and family history of the case is important, special inquiry being made regarding the affection of any family connection by malignant disease. The physical condition of the patient (cachexia) will frequently indicate the probably malignant form of the disease, although many cases of positively malignant growths have occurred without any apparent physical or constitutional infection. The age of the patient may indicate possible malignancy, a high percentage of malignant orbital tumors occurring early in life. The time of onset is important in indicating the character of the disease, a tumor recently appearing, which has attained great size in a comparatively short time, being much more apt to be malignant than one of slower growth, although even a malignant tumor may be of slow growth, while it remains in the posterior portion of the orbit behind the globe and ocular muscles. When the surrounding tissues have been involved in the orbital growth or have become a part of it, the question of its malignancy is almost settled, as a benign tumor rarely, if ever, extends. The presence of pain is more common in malignant disease but may be present in any case providing the growth has attained sufficient size to cause pressure upon the eyeball and stretching of the nerves. The character of the protrusion and its extent is, if a tumor exist, generally more marked in a given direction, and not directly forward and uniform, as is frequently the case in other conditions. The mobility of the eyeball is more extensively impaired in tumor than in other conditions, and in malignant disease is frequently affected very shortly after the onset, even before the proptosis is marked, while in other conditions presenting excessive exophthalmus an almost normal muscular action may be present. The location of a tumor within the eyeball, or attached to it or to the optic nerve, is an indication for immediate operation before the disease spreads to the surrounding tissues or cavities; the attachment to the eyeball or to the optic nerve is indicated by the proportionate ratio of mobility to the protrusion, the mobility in malignant disease being much more impaired than would be indicated by the amount of the prominence of the eyeball. The condition of the eyeball itself, even when not diseased,

may be an indication for immediate interference, as frequently the pressure effect is cause of excessive pains, congestion, edema, inflammation, and strangulation, endangering the integrity of the globe from malnutrition or induced disease.

The effect of the stretching of the optic nerve upon the vision varies with the different cases and conditions ; the sight is, however, always more or less blurred, and may be nearly, if not entirely, lost. Although it can not always be determined positively that an orbital tumor exists, and especially what the probable variety of the growth may be, the diagnosis may be made more readily after the exclusion of any possible cause for the condition other than some variety of abnormal growth.

The presence of a tumor of the orbital cavity having been ascertained, the first and most important consideration is, has it a benign or malignant character? While surmise is profitable and a probable diagnosis may be made, certainty can only be acquired by a microscopical examination of some portion of the growth itself. The diagnosis is rendered more difficult in consequence of the location of these tumors, which is frequently, in the early stages at least, so far back in the orbit that thorough digital examination is not possible. The point of origin is most important, not only in indicating the probable character of the tumor, but also in determining the proper course of the operative treatment to be pursued. The rapidity of the onset of the growth is of great importance, especially if it be accompanied by excessive pain, with extensive protrusion of the eyeball and if the mobility of the globe and the vision be decidedly impaired. The invasion of, or the onset in, any of the surrounding cavities is extremely serious, probably indicating the impossibility of the removal or evisceration of the growth in its entirety. The operation indicated, in nearly all cases of tumor of the orbit, is the removal of the entire growth ; if the location of the tumor will permit it the operation may be made from behind the eyeball, leaving the organ in situ after the procedure. If the tumor involve the eyeball itself, or is so extensive that it precludes the possibility of its complete extirpation without the removal of the eyeball, the entire mass must be removed. If any portion of the tumor remain after operation the cavity must be thoroughly cauterized with the galvano-cautery or the application of a strong caustic paste. In advising operation the most important considerations are: If the tumor is benign ; is it endangering the integrity and vision of the eye? Will it possibly disappear without operation? May it be a benign tumor which presents the symptoms and character of a malignant growth? If the tumor is decidedly malignant the important question is the probability of its complete removal, for if not likely to succeed in the entire evisceration of an orbital tumor (and some of the malignant tissue may remain within the orbit or surrounding cavities and can not be removed or destroyed), it is almost certain that the growth will recur with marked rapidity and much more extensively than if it never had been operated upon, and that the patient will succumb much sooner than would otherwise have been the case. The tumor, even if malignant, if confined by the presence of the eyeball and the surrounding tissues will be of comparatively slow growth. Even though there is progressive protrusion, loss of motion and sight, irritation, inflammation, edema, strangulation, and perhaps subsequent disintegration, a tumor which can not be entirely removed should not be operated upon unless the unbearable pain, distressing discharge, and bleeding compel it ; for the condition is generally much worse very shortly after the operation has been performed, and the death of the patient is hastened without compensating benefits.

#### SMALL SPHEROIDAL AND OVOIDAL CELLED SARCOMA OF THE ORBIT.

*Case No. 1.*—B. D., age 6, August 3, 1886. A strong, well-developed boy, giving a previous history of good health, no cachectic appearance, and no history of malignant disease, either in the paternal or maternal ancestors. One year previ-

Fig. 1.

FIG. 2.—A, cells from teased tumor; B, degenerated cells from the same.

FIG. 3.—Capillary blood vessels with hyalin degeneration of the walls.

CASE NO. 2.—MYXO SARCOMA OF THE OPTIC NERVE WITH HYALIN DEGENERATION.

ous to the present visit he had an abscess, which broke and discharged at a point 1 inch below the left eye, over the superior maxillary bone. The discharge continued for three days, and was estimated to have been about one-half teacupful in all. The abscess healed kindly, the swelling diminished, but for some time the cicatrix adhered to the bone. At present the skin is movable, and a very small scar marks the point of rupture. Eight months ago the mother first noticed a prominence of the left eyeball, which has gradually increased until the present time; the increase having been much more rapid during the past three months. There is a slight pain occurring once or twice a day; at other times the patient has no discomfort, and does not suffer from headache. The examination discloses the left eyeball displaced forward, downward, and inward, one-half inch anterior to its normal position; the corneal sensibility is not diminished; the pupil is slightly contracted, but responsive to light; the eyeball is reddened; there is considerable lachrymation and some mucous discharge. Above the eyeball and to the temporal side, palpation reveals a somewhat movable dense mass, apparently about the size of a Brazil nut; the mobility of the eyeball is only slightly impaired in some directions; the vision equals: R. V. =  $\frac{20}{20}$ ; L. V. =  $\frac{20}{30}$  N. I. with glasses. Ophthalmoscopic examination reveals a normal fundus.

August 17: Dr. H. Knapp examined the case in consultation, and advised immediate operation. Since last record the growth has developed rapidly, and during the past five days an increasing haziness of the lower quarter of the cornea has appeared, with a markedly roughened and yellowish area near the limbus and also considerable conjunctival chemosis.

August 23: Operation under ether; a crescentic incision,  $1\frac{1}{4}$  inches long, was made through the upper lid, just below the eyebrow; the dissection was continued with the handle of the scalpel, and the tumor peeled out readily; the bone on the temporal side of the orbit was rough, as though it were denuded of its periosteum. The tumor, a dense inelastic mass, was  $1\frac{1}{8}$  inches long and three-quarters of an inch in diameter in its widest part; it was somewhat lobulated, having an anterior and a posterior portion and decreased in size as it was more deeply seated in the orbit. The wound was closed, several strands of catgut being placed in the cavity to facilitate the drainage.

August 24: Since the operation constant but slight oozing has continued; the lids are edematous, the conjunctiva less chemotic than before the operation, the cornea is still hazy, but the roughness and yellowish appearance is improving.

August 27: The stitches were removed; the wound had healed except at the most dependent point kept open by the catgut drainage. There had been but little pain following the operation, and the temperature varied from  $99^{\circ}$  to  $103^{\circ}$ ; the conjunctival chemosis continues to grow less and the appearance of the eye has decidedly improved.

August 28: The discharge from the wound is of dark color, but not at all odorous; the catgut drainage was removed and a small rubber drainage tube inserted in its place; a pressure bandage was then applied for the night, hot-water applications having been used continually previous to this time.

September 8: The patient has improved steadily since last record, the wound having healed kindly from the bottom and entirely closed, the eyeball being normal and in its proper position, and the vision perfect in each eye; the patient was discharged cured.

December 12: Three months after the patient left the hospital apparently cured, he returned with a growth evidently of the same character as the one removed, but much smaller, situated below the eyeball and to the nasal side. An immediate operation was advised. The patient, however, passed from observation and unfortunately no subsequent history of the case could be obtained. Dr. T. Mitchell Prudden, of New York, made a microscopical examination of the growth, and his report is as follows: "The tumor is of an irregular ovoidal shape about 2 inches long and 1 inch in diameter in the thickest part; its texture is firm and dense.

*Microscopical examination.*—The tumor mass consists for the most part of spheroidal and elongated cells. These cells are in most places closely packed together, but in some parts narrow bands and fascicles of fibrilated basement substance run between and among them. The cells are all small, and the prevailing form is the spheroidal; the tumor is but moderately vascular. The anatomical diagnosis is accordingly: small spheroidal and ovoidal celled sarcoma.

#### MYXO-SARCOMA OF THE OPTIC NERVE WITH HYALINE DEGENERATION.

*Case No. 2.*—C. A., aged 22. When 12 years of age she was operated upon for tumor of the optic nerve, which had been first noticed six years before. The case, which was very interesting and unusually rare, was reported in the Archives of

Ophthalmology, Volume XIV, Nos. 2 and 3, 1885, with illustrations and microscopical examination, by Dr. T. Mitchell Prudden, of New York. The child, when first examined in 1883, had an exophthalmus of 13'', with accompanying inability to close the lids and many disturbing symptoms, which had gradually increased during the past six years, although pain and increasing discomfort had not appeared until the past year. The eye had been sightless for five years and six months; the general health of the patient is and always has been extremely good. The case is again mentioned to record the fact that at this time, ten years after the removal of the growth, there had been no return, even though it had been considered possible that all of the structural material had not been entirely removed at the operation.

#### RECURRENT CARCINOMA OF THE ORBIT FOLLOWING ENUCLEATION.

*Case No. 3.*—S. F., 2 years; March, 1892; United States. The child, of Irish and Scotch parents, had enjoyed good health until 1 year of age. There was no history of malignant disease either in the family of the mother or father. One year ago the mother first noticed eye trouble, which she considered an inflammation of the eye, probably caused by cold. When carefully questioned, however, she stated that the eye had not appeared just right from the time the child was 3 months old. She described the pupil as widely dilated, stating that the blue part was absent and that the eye looked peculiar. During the last year the eye has increased in size gradually, until about four months ago, when it commenced to enlarge more rapidly, and the child began to complain of pain. Enucleation was advised by an eminent oculist of an adjoining city, but was not permitted until January 5, 1893, when the eyeball had protruded excessively. Bleeding had occurred, and there was a constant discharge of ichorous pus. The enucleation was delayed so long, in consequence of the objections of the parents, that a successful operation was doubtful. It was, however, performed by the physician above alluded to. For three weeks the orbital cavity seemed to be in a perfectly healthy condition, and the parts appeared to have healed kindly; after this time the orbit began to fill up again, and from that time, about February 1, until March 9, when first seen, it increased very rapidly until it finally emerged from between the lids. The tumor bled frequently and constantly discharged a bad-smelling, ichorous pus. The child was in an extremely restless and enfeebled condition and it died of hæmorrhage and exhaustion three days after.

#### ORBITAL SARCOMA ORIGINATING IN THE NASAL CAVITY.

*Case No. 4.*—Miss V. R.; aged, 22; November 15, 1890. First saw patient on above date; at that time she had slight ptosis and a very little paralysis of the left side of the face. She had constant lachrymation from the left eye; was rather delicate; although not frequently ill, was thin and somewhat anæmic. Bowman's operation for opening the lachrymal sac and subsequent probing was advised. The operation was performed in the usual manner and a No. 8 Bowman's probe introduced. For the first four weeks after the operation the patient was seen and the probe passed twice each week; from that time until the 5th of September, nearly one year, she was seen every week or two and the probe passed, with temporary relief, but the lachrymation always persisted to some extent. There was never any unusual bleeding from the nose after probing. The probes were increased in size gradually to No. 13 Bowman's.

On September 5, 1892, she first complained of difficulty in breathing through her nostrils. Examination disclosed a complete occlusion of the left nasal passage; the inferior turbinated bone was covered with hypertrophied mucous membrane and the post pharynx on the left side was apparently filled and closed, so that she could not inspire or expire with the right nostril closed. The removal of some of this hypertrophied tissue was advised, and the operation performed without having inflicted unbearable pain; it was followed by excessive hæmorrhage; the amount of tissue removed was not great; the canulated knife of Dr. Smith was used in operating. There was constant oozing from the nose, and on the second day after the operation severe inflammation accompanied by excessive swelling and violent pain supervened; the inflammation extended to the antrum, the frontal sinuses, and also through the Eustachian canal to the ear. This inflammation subsided very slowly and was attended by severe pain. The patient was treated by local applications and warm douching. In about two weeks the trouble had practically subsided, there was but slight improvement in the nose, although a partial inspiratory effort could be made, but expiration was completely suspended. The peculiar friable feel of the membrane of the nose suggested the pos-

FOLLOWING ENUCLEATION.

CASE No. 4.—ORBITAL SARCOMA ORIGINATING IN THE NASAL CAVITY.

sible malignancy of the growth and the patient was referred, with a history of her case, to Dr. F. H. Bosworth, of New York, who made further operations upon the nose which on each occasion was followed by extremely excessive hemorrhages, although his opinion was at that time that the tumor was of a non-malignant type. One month later, in a letter written to Dr. S. F. Wiley, who originally had charge of the case, Dr. Bosworth stated that he then considered the growth to be possibly a myxo-sarcoma and thought it probable that the tumor might have been induced by the probing of the lachrymal duct, although he was not able to locate the point of origin at a point near its opening. The Doctor also suggested the possibility of the excessive pain in the ear being due to pressure on the sphenopalatine nerve, although the inflammation of the middle ear by extension had been considered sufficient to produce the pain. The patient passed from observation from October, 1891, until June, 1893, about eighteen months, when she again presented herself for treatment, enucleation of the left eye having been advised in consequence of an exophthalmus which had gradually increased during the past year and had developed to such an extent that the proptosis of the left eyeball was equal to about 1 inch. The eye was entirely sightless; the cornea in a semi-sloughing condition; there was constant lachrymation and purulent discharge and at intervals distressing pain in and about the eye. The right eyeball had also recently increased in prominence and its vision decidedly diminished, the nose was completely occluded, no inspiratory or expiratory effort being possible through either nostril. The patient seems also to have lost somewhat in mental power and at times is considered by her family to act in a very peculiar manner. In consequence of the extent of the disease being so great and the possibility of a radical operation so slight, any operation was not considered advisable and the patient returned home.

#### TRAUMATIC EXOSTOSIS OF THE ORBIT.

*Case No. 5.*—M. E. M., colored, aged 25, married. A strong, healthy woman, with a good family history, and her husband well and free from specific taint. She has had two children, one of which was stillborn and the other died in ten or fifteen minutes. There is no indication of, and she denies, specific disease. Three years and six months ago she was kicked on the left side of her face, causing a contused wound of the left upper eyelid and a general swelling and ecchymosis about the left eye; the wound healed and the swelling entirely disappeared in about a month. Six months after this time her attention was called to a "swelling" on the left side of her face, at the edge of the orbit near her nose, which she had failed to notice. This tumor has slowly increased in size, absorbent and alterative medication apparently having no beneficial effect. Two months ago she first noticed pain in the growth, which has at intervals been so severe as to prevent sleep. She also suffers from occasional frontal headaches. The patient has no tenderness in the region about the growth, but immediately over it pressure produces some pain; she has an epiphora, but no inflammatory disease of the eye; the nasal passages are free and clear. The tumor, which is hard and immovable, is situated over the edge of the orbit and extends from the nasal bone, covering part of the anterior surface of the superior maxillary. The tumor was about  $1\frac{1}{4}$  inches in length, and in size and shape very much like a Brazil nut; a linear depression could be felt between it and the nasal bone, the surface was slightly nodular, the skin was not adherent to it, there was some swelling of the adjacent soft parts. Operation was advised and performed. A T-shaped incision was made just below the lower eyelid, over the tumor,  $1\frac{1}{2}$  inches in length, and at right angles to this an incision three-quarters of an inch in length just over the linear depression between the tumor and the nasal bone; the periosteum was stripped off and disclosed the growth, which was somewhat cancellous in some parts, while in others it was compact and dense. The growth could not be separated en masse, and in chiseling was broken off in many pieces, as shown in the specimen herewith presented. The edge of the orbit and anterior surface of the superior maxillary bone were thoroughly cleared down to the healthy bone with a pair of sharp-cutting gouge forceps. The wound, which was antiseptically dressed, healed kindly, a slight purulent discharge occurring on the fifth, sixth, and seventh days from the most dependent portion of the wound, its edges having been separated for the purpose. The deformity was removed, a slight scar only being left, which after cicatrization adhered somewhat to bone; there has been no pain and no subsequent increase of bone tissue to present time, six months after the operation.

#### SPONTANEOUS HÆMATOMA OF THE ORBIT.

*Case No. 6.*—Miss Z., aged 14, November, 1892. Was first seen November 12, 1892, having been referred by Dr. George T. Welch, of Passaic. The right eye was

excessively protruded, the exophthalmus being so great that there was severe pain. The eyeball was displaced downward, forward, and outward, fully three-quarters of an inch in front of its normal plane, a tense swelling resembling a malignant tumor of the orbit was situated above and to the nasal side of the eyeball. Three days before her first visit she suddenly felt a severe pain in the right eye, which was immediately followed by the tumefaction. There was no ecchymosis present; the mobility of the eyeball was greatly impaired. An exploratory puncture was advised and performed with a hypodermic needle, which was thrust into the tumor; a syringe of dark-colored, liquid blood was withdrawn. The pain was relieved at once and the subsequent absorption was very rapid, the exophthalmus having entirely disappeared in about two weeks. There was no subsequent ecchymosis or pain. The removal of a portion of the extravasated blood by an hypodermic needle in such cases would seem to be very desirable, as the process of absorption is retarded and can not be satisfactorily established until the excessive pressure is relieved.

#### CARCINOMA OF THE NASAL FOSSA EXTENDING TO THE ORBIT AND SURROUNDING CAVITIES.

*Case No. 7.*—Mrs. M., aged 63, a strong, healthy woman, presented herself at the Paterson Eye and Ear Infirmary for treatment. For the past two months she has suffered from inability to breathe through her nose, and for the past ten days she has had violent pains over the frontal sinuses which were very sensitive to the touch. She has no knowledge of any malignant disease in any member of her family or relations. On examination both the right and left nasal passages were found to be filled with masses of a new material which was friable, nodular, and bled profusely when touched. The point of origin seemed to be from the vicinity of the turbinated bones and vault of the nasal passages. The growth was considered malignant. The pain had, during the next two weeks, increased to such an extent that an operation was performed for its relief. The operation consisted in the cleaning out of all the tissue possible from each side of the nose with a snare and the forceps. A large quantity of tissue was removed, including the turbinated bones which were within the tumor mass. The bones were very brittle and the growth came away readily, one large mass from each nostril, and many small pieces. There was considerable hæmorrhage, and oözing continued for three days, after which time the irritation of the operation gradually subsided, the swelling and pain over the frontal sinuses was relieved, and the patient remained very comfortable for five weeks, during which time the growth had gradually increased until finally it became more painful than ever before, and a marked prominence of the right eye began to develop. The growth was examined microscopically by Dr. J. W. Williams, who submitted the following report: "I have made and examined sections of the growth which you sent me, removed from the nasal fossa of Mrs. M., and found it to be carcinoma, the cells being for the most part of the squamous type." The patient desiring further operation in consequence of the unbearable pain was referred to the New York Cancer Hospital, where her right eye and part of the bones of her face were removed, but the growth returned. She was operated upon three times in all, and she finally died, six months after her first visit, from a recurrence of the disease and exhaustion.

#### A CASE OF ENOPHTHALMUS TRAUMATICUS.

By LOUIS F. LOVE, M. D., of Philadelphia, Pa.

*Ophthalmic Surgeon to St. Mary's Hospital, etc.*

I wish to present to the attention of the Congress the description of a case of enophthalmus traumaticus. The right eye presents the appearance of being sunken in the orbit. The under lid, with its loose and baggy folds, shows an almost complete absorption of the underlying fat; and that this condition of absorption extends to the whole cushion of fat in the orbit is evident from the fact that the ball is retracted from 6 to 7 millimetres. The retraction gives the eye the appearance of an artificial eye, an appearance which is enhanced by the apparent smallness of the globe. The globe is in reality, however, the same size as its fellow. Microphthalmus was absolutely excluded. The old scar, which is visible on

TRAUMATIC ENOPHTHALMIA.

TRAUMATIC ENOPHTHALMIA.

the nose, has nothing to do with the present disease. The history of the case is as follows:

P. McC., age, 35, was struck with the fist in the right orbital region in March, 1893, the blow being quite a severe one and causing a large swelling of both lids. There was no external wound. The swelling remained for about two weeks and was not treated except by domestic remedies. After the subsidence of the swelling he noticed that the eye appeared smaller than its fellow, and this condition had continued up to the time he presented himself for treatment, three months after the date of the injury. At no time had he suffered pain in the eye itself, and vision was excellent. O. D. V. =  $\frac{6}{8}$ ?? D. = 0.50 18c. 46c. O. D. V. =  $\frac{6}{8}$ ? D. = 0.50 20c. 48c. On examination the globe is found to be retracted 6 or 7 millimetres, but is normal in size; there is no apparent paralysis of any of the ocular muscles, but the movement of the globe was markedly limited in all directions. The lower lid is thrown into folds and presents a flabby appearance. There is no ptosis, and the patient states that at no time was double vision present. The right pupil is about 2 millimetres in size, the left about  $2\frac{1}{2}$ , both actively responsive to light. Ophthalmoscopic examination showed media clear, disk oval, axis  $90^\circ$ , good tint, vessels normal in size and carrying good blood. In a word, there was apparently no gross pathological changes.

The case which I have thus briefly presented appears to be almost unique. The cases heretofore reported have almost invariably been connected with fracture of some of the bones of the orbit, or were the result of age or disease. In this case there was no evidence whatever of fracture, and all the circumstances pointed to its having resulted from direct violence in a young and healthy man. The literature upon the subject is exceedingly meagre. Dr. Hansell, in reporting a case to the Philadelphia County Medical Society\* in which a fracture of the orbital plate of the ethmoid bone existed, has collected what little there is. The older authors are silent on the subject of traumatic enophthalmus, with a few exceptions, and only refer to enophthalmus produced by disease in an incidental manner. Two cases reported by Gessner (*Archiv für Augenheilkunde*, Bd. XVIII, Hft. iii), and quoted by Dr. Hansell, are similar to mine. In both of these cases the orbital region was lacerated by injury, and a few weeks later enophthalmus of the ball was noted. In both cases the condition remained permanent. A plausible explanation of the condition is that a cicatricial contraction of the retrobulbar fat and cellular tissue occurs as the result of inflammatory reaction, following a wound in this neighborhood. In the case I have the honor to report there was no evidence of wound or deep-seated lesion, though whether the inflammation of the cellular tissue about the eye could have extended to retrobulbar tissue and could have been followed by cicatricial contraction, or more probably by absorption, can not certainly be stated. It is possible that the injury caused a general infiltration of inflammatory products throughout the orbital tissue, and that when these products were removed by absorption, that much of the normal tissue was absorbed with them. But what should cause such an abnormal absorption, and, if such should be the cause, why do we not see more of such results following a blow in this region? We know very little of the trophic nerve system, or even of the normal method of absorption in the orbital region, yet physiological investigation has furnished some facts which may bear upon this case. I am indebted to Dr. Charles K. Mills for literature which he has placed at my disposal. Claude Bernard called attention to the fact that the contraction of the pupil after division of the sympathetic is constantly accompanied by retraction of the globe of the eye, flattening of the cornea, and decrease in the size of the palpebral fissure. The same phenomena he saw also after division of the anterior roots of the two first dorsal nerves and after section of the spinal marrow at the level of the first and second dorsal vertebræ. Irritation of the divided sympathetic or of the peripheral ends of the several anterior roots gave opposite results, prominence of the globe, bulging of the cornea, and enlargement of the palpebral fissure. H. Muller (musculus orbitalis—smooth muscular fibres found in the

\* Proceedings of the Philadelphia County Medical Society, Vol. XI, 1890.

membrana orbitalis)\* discovered in the anterior orbital fissure a reddish gray mass consisting of bundles of unstriated muscular fibre with elastic tendons analogous to the orbital membrane of the mammalia. He supposed that its action is to protrude the eyeball. It is supplied by fibers from the sympathetic, and irritation of the latter in the neck has been found to cause protrusion of the eye, perhaps through the action of this muscle.† Sappey has described similar muscles in the orbital aponeuroses.‡ The well-known experiments of Euhlenberg and Guttmann on the cervical sympathetic may also be referred to.§ In conclusion, I will state that the case has been kept under observation and any further changes will be noted carefully. The condition is, of course, irremediable by surgical or other means.

### FURTHER OBSERVATIONS ON THE EYE OF THE NEGRO.

By CHARLES W. KOLLOCK, M. D., of Charleston, S. C.

In a former paper on this subject it was concluded that the eye of the negro had deteriorated since he became free, and that this was due to the following causes: (1) Syphilitic infection; (2) lack of good and sufficient food and clothing; (3) total disregard of sanitary and hygienic surroundings; (4) frequent sexual intercourse with whites of low condition which has produced the mulatto, who inherits the weaknesses of both races, and therefore is rarely healthy, but generally syphilitic, scrofulous, and tuberculous; (5) education implanted upon such a rotten foundation has produced its ill effects, such as myopia and attendant evils. Syphilis has caused widespread destruction among them, and it is not an exaggeration to repeat that but few remain who do not show symptoms of infection. The eyes, especially, have suffered from this disease, and blindness is increasing rapidly. Ignorant and careless of consequences, they rarely consult a physician when the disease is in its incipency, so that when seen iritis is usually well advanced, synechiæ firm, pupils occluded, and general inflammation of the uveal tract and choroid is not unusual. When there is keratitis, and this occurs in 37 per cent of all their diseases of the eye, ulcers have extended over the cornea and eaten into the layers proper, and perforation is the rule. When it is realized that so large a percentage have keratitis in some form, and that they rarely seek advice until serious injury has been done, it is not difficult to understand how fast impaired vision and blindness are increasing. Kerato-malacia associated with xerosis of the conjunctiva is a frequent and interesting condition seen in negro children, and more commonly among the blacks than mulattoes. It is not often found in adults, and in Charleston has never been seen among the whites, though there are many who live in similar conditions and who have like surroundings. There can be no doubt but that the disease is due to a lowered vital condition, and it usually occurs in weakly children from one to eight years of age. Some show undoubted signs of inherited syphilis, others are scrofulous, and some tuberculous, with cavities in their lungs and deposits in the mesentery, while others do not appear to have any bodily affliction; but all are night-blind, and this more than any other symptom induces the parents to bring them for treatment. It has been thought that perhaps malaria was a factor in its causation, but examination of the blood so far has not proved anything worthy of note. The existence of a bacillus|| has been suspected. The negro lives commonly on hominy (grits), rice, fish, and

\* Billings's National Medical Dictionary, Vol. II.

† Soelberg Wells by Bull, A Treatise on Diseases of the Eye.

‡ Sappey's Anatomy, 1876-1879.

§ Journal of Mental Science, Vol. XXXIII, 1883.

|| It is stated that the bacillus has been found by Dr. Weeks, of New York.

bad hog meat, and it is possible that the kind of food may have something to do with the condition.

The whites do not eat as much fish, and the quality of hog meat is better than that used by the negro, who will frequently buy strong smelling meat in preference to that which has no odor. Treatment does much for those in whom the cornea is slightly affected, but it has been the experience of the writer that when the entire cornea breaks down and suppurates it avails nothing and the patient soon dies. Malaria is undoubtedly a cause of keratitis among them, and when such is the case there will be periodic exacerbations. These cases are rapidly improved by large doses (gr. xx) of quinine given at short intervals for several days in succession. But in all these cases of corneal trouble specific treatment will be of great value. The negro is a curious being; he will sit, ax in hand, on a pile of wood and freeze to death, and he will hold a prescription which can be procured free of charge, and yet not have it filled, so that treatment is not always satisfactory, nor can one depend upon him to carry it out. But for certain things he has a predilection, and one of these is for "salves." Any greasy dirt that he can rub in will afford him pleasure. Therefore, taking advantage of this weakness, it is best to begin treatment with mercurial inunction; than which there is no better. He will faithfully rub a drachm of this into his skin twice a day, and the results are magnificent. It is food and medicine; he responds beautifully, and the efficacy of drugs seems assured.

They seem to bear mercury better than the whites, and inunction may at times be continued for two weeks or longer. Conjunctival inflammation of a mild character is more frequently seen among the mulattoes, but this may be due to the fact that refractive errors are more common with the latter, and also that they use their eyes more for trying work than the blacks do. Trachoma is equally rare among both blacks and mulattoes, but undoubtedly occurs. Strange to say, ophthalmia neonatorum is not very common among them. The gentlemen who have done the practice for the poor in Charleston say that it occurs in the blacks less frequently than among the whites. Certainly gonorrhœa does not seem a very prevalent disease with them. Recently two cases of leprosy have been seen in mulatto men by the writer. One man was about 60 years old and the other 25. No other members of their families were affected, nor were they related. Both had the nodular infiltration along the eyelids and the ciliæ had dropped out. In the older man the diffused progressive opacification described by Hulanicki was shown. It extended upon both corneæ from the upper margins to about the centers. The surfaces were smooth, there was no inflammation or photophobia, and the haziness was either between the conjunctival layer and Bowman's membrane, or involved the latter. In the younger man was seen the other mode by which the disease affects the eye—the nodular infiltration of the cornea. This, Hulanicki says, is seldom a primary affection of the cornea, but usually extends from the sclera. This patient had also some signs of syphilitic affection, as the bones of the nose had been destroyed by ulceration, but leprosy and syphilis seldom coexist in the same person. Refractive errors are met as commonly among the mulattoes as the whites, but as yet myopia is not quite as frequent in occurrence, though it is undoubtedly increasing. In the pure black, refractive errors are the exception; myopia has never been seen by the writer, but as their education advances they will at no distant date have the civilized eye.

---

#### DISCUSSION.

Dr. Burnett, of Washington, said he had been interested in the eye of the negro for many years; had published at various times papers on the subject since 1876, and he was glad to find that the experience of Dr. Kollock agreed in all essential

particulars with his own. His experience in Washington, however, has not shown that syphilis is yet so destructive as it appeared to be in Charleston.

Dr. Belt, of Washington, D. C., said that he had seen many cases of ophthalmia neonatorum among the negroes, and that it was not uncommon. He thought it more severe among the whites and mulattoes than among the pure-blooded negroes. He had found iritis very common and nearly always from syphilis, but it usually responded well to treatment.

Dr. Chisolm said that Baltimore, the city in which he lived, had a colored population of 45,000, and that in the books of the Presbyterian Eye and Ear Charity Hospital he has recorded upward of 8,000 cases of disease. These he had not yet collated, but would do so at some early day. Syphilitic troubles were commonly met, especially as iritis, and often with gummata. He thinks glaucoma more common among them than in the whites. Purulent ophthalmia of the newly born he does not often see among the blacks, notwithstanding their general disregard of cleanliness. As to the two cases of leprosy which Dr. Kollock had met with, he would state that in his earlier medical career when he practiced medicine in Charleston for fifteen years he knew of five cases of leprosy, some of whom had been his patients. They were all whites, all relatives, all sporadic cases in large families; most of them among the best people and occurring in early adult life. These cases ran through all the peculiar phases of the disease, with eye, throat, and bone complications, terminating fatally. They were usually members of large families, from healthy parents, with no history of leprosy in the family. During the years that the disease was running its course these persons were in no way isolated, but lived on the most intimate relation with the other members. Some were old enough to be married before the leprosy was developed. Contagion was never considered in the house nor has any case ever shown itself from these constant and close intimacies. The leprosy in these families began and ended with the isolated case, and hence established in my mind the belief that the disease was not contagious.

In closing the discussion Dr. Kollock said that undoubtedly the large percentage of corneal cases seen in Charleston was due to the carelessness upon the part of the negroes in not seeking medical advice earlier. That he found the negro responded well to treatment, but it was difficult to make him carry it out thoroughly.

---

### THE TREATMENT OF TRIQUIASIS AND DISTRIQUIASIS BY LIFTING THE EYELID.

By JUAN SANTOS FERNANDEZ, M. D., of Havana, Cuba.

Triquiasis and distriquiasis are generally the results of prolonged irritation of the free borders of the eyelids; they are consequently most commonly observed in ill-accommodated persons who are more or less exposed to granulations and other inflammatory diseases of the eye that are due to lack of hygiene. This disease has been studied since long ago and many methods of treatment have been proposed against it; epilation and application of calcium sulphite have been employed together with the ablation of the free border. These procedures are, however, of little value, the first being too long and the second non-physiological. A change of direction in the eyelashes is to be preferred. This method, advised by Celsius, which has been since modified by Sorelle, Knapp, and others, is not acceptable on account of the great number of eyelashes which may necessitate the procedure. Moreover, the results only last three months, when it is necessary to perform a new operation. It has been considered better to change the direction of the implantation area of the eyelashes. The methods of Arlt and others have been devised with the view of real-

izing this suggestion. The methods that I propose do not interfere either with the eyelashes or with their implantation area. I only endeavor to change the position of the border of the eyelid by placing a wedge of tissue under the external corner of the eye and maintaining it in position by means of a suture. I desire to expose briefly the facts that induced me to devise this procedure.

The 2d of July, 1891, I was visiting the ophthalmic clinic of the faculty of Lyons under the direction of Prof. Gayet. He stopped before one of the beds and said: "This is a countrywoman of yours on whom I have performed tarsoplasty as a remedy against entropion." It was a girl of Cartagena, who had contracted granulations and entropion in Algeria. I became greatly interested with the new operation, which attempted to resolve the treatment of a disease which I had been sometimes unable to master; and at other times, after having succeeded in removing the symptoms, I had seen them reappear after a year or two. I begged Prof. Gayet for a demonstration, which was accorded, and he recommended to me his work on the matter.\* Gayet supposed that the diseased tissue being a scar, the transplantation of a flap of skin would remove all trouble. He desired to cover with skin the internal or posterior surface of the superior eyelid, and he expected that the eye would perfectly tolerate the contact of the new epithelium. His object was, therefore, to lift the border of the eyelid in a way to prevent the eyelashes coming in contact with the cornea. I endeavored to perform Gayet's method, but I met too many difficulties in keeping the sutured flaps in place and I devised the new method.

The observations that I have made prove that in many cases the flap failed to heal and occasionally was destroyed by gangrene. The troubles disappearing even under these conditions, I consequently came to the conclusion that success might be obtained even without complete healing of the sutured flap. I thought it would suffice to slit the external canthus of the eye, dissect the superior border 1 centimetre high, and place underneath a small flap of skin dissected from the temple, and then restore the canthus with a suture. The superior eyelid would thus be increased in thickness and its free border would be situated at more distance from the cornea. The method is based on the anatomy of the obturator muscle of the eyelids. This muscle is provided with fixed and movable insertions. The first are attached to the base of the orbit by means of four portions which embrace the lachrymal bag. The second (movable) are fixed in the deep surface of the skin which is situated in the external portion of the orbital region precisely at the external angle of the eye. These fibers are curved and their concavity is directed toward the palpebral opening. But few fibers of the superior eyelid continue to the inferior one without becoming adhered to the external portion of the region. This condition renders possible the section of the angle without interfering with the functions of the sphincter. This change in the position of the border of the eyelid is the basis of the method performed in the cases that I am going to relate.

Mrs. M. P. G. was seen on August 26, 1880, suffering from granulations and triquiasis. Epilation was tried without success. She was operated on May 22, 1892; a frontal lambeau 4 cm. long was placed under the eyelid after section of the external canthus having revived the mucous surface. To-day she is completely relieved, and no difference is to be detected between this eye and the healthy one.

Mrs. S. B. P., æt. 61, applied on September 8, 1892. She has suffered for thirty-one years. The corneæ were opaque on account of pannus, which had resulted from the contact of the superior eyelids. Tarsoplasty was performed on October 11, 1892, according to Gayet's method. A flap of skin was dissected from the temple and sutured to the posterior aspect of the eyelid. Five days after the stitch at the end gave way, the flap becoming free. Two days after some more of the suture gave way, and the flap being imperfectly attached it was decided to excise it. This was done, and only 2 cm. were left. Twenty days after the patient was greatly relieved.

---

\* Annales d'Oculistique.

S. H., æt. 30, had from childhood a deviation of the eyelashes, which was the result of traumatism. He had submitted to several operations without success. Ectropion of the lower eyelid was resorted to; tarsoplasty being afterwards performed with the view of preventing lagophthalmus. Operation was performed as usual, the suture being partially made with metallic thread. Æsthetically considered, the result was not a very good one, but the troubles were removed enough to allow of rude work.

E. J. A., Chinese (No. 25708), had granulations and distriquiasis, with pupillary atresia. Tarsoplasty was performed by Gayet's method and antiseptic bandage was placed and the flap healed in position, but a little too high. The border of the eyelid was not, therefore, sufficiently raised, and the eyelashes continued to disturb the cornea. A new operation was proposed and was not accepted by the patient.

A. C., Chinese, September 16, 1891; total leucoma, atrophy, chronic conjunctivitis, caused by distriquiasis. Tarsoplasty was performed. A flap was dissected from the temple, the external comisure incised, and suture applied. Three days after the flap was still adherent, but in March the patient was newly examined and but traces of the flap were found. The troubles were, nevertheless, relieved.

C. G. P., of Canarias, æt. 22, May 14, 1888—granular conjunctivitis, triquiasis, and distriquiasis of both eyes. She has applied daily for five years. Epilation and other treatments proved unsuccessful. February 9, 1892, I resolved to perform the operation which I had devised instead of that of Gayet. I accordingly dissected a small flap from the temple, which I placed under external angle; several points of suture finished the operation. Immediately after operation the free border of the upper eyelid was seen to be a little before the lower one. Later, however, this condition became less marked, sufficient difference remaining how—how—just enough to prevent any trouble arising from the contact of the eyelashes.

C. G. P. is the same person, the operation involving the left eye. The operation was the same, though greatly simplified. The flap was 3 cm. long and was sutured to the eyelid after incision of the angle. The success was as complete as in the other eye.

From the perusal of the foregoing chapter it will be seen: (1) That the surgical operation that I propose is designed for the correction of triquiasis, distriquiasis, and entropion of the upper eyelid. (2) I reached this object unexpectedly whilst trying to perform tarsoplasty according to Professor Gayet's method. (3) I find the reason of the success in the absence of fixed insertions in the external extremity of the orbicular muscle. (4) In certain cases of distriquiasis, the eyelashes grow in a wrong direction, and, when fully developed, they rest against the border of the inferior eyelid. (5) Patients with granulations who had not been able for a long time to perform their duties are enabled after the operation to resume their work. (6) I feel satisfied that a greater number of operations will bring new modifications to the preceding, which is already greatly simplified.

#### A CASE OF CYSTICERCUS OF THE VITREOUS.

By W. CHEATHAM, A. B., M. D., of Louisville, Ky.

This affection being so rare in America, England, France, and countries other than Northern Germany, I feel justified in reporting a case that has come under my observation this week.

Mrs. F., aged 42, of Irish parentage, consulted me May 22, 1893, concerning her left eye. January last she had some severe acute inflammation of her left eye in which there was intense pain and edema of the lids, which lasted for some weeks. She now has vision of left eye  $\frac{1}{40}$ , with no improvement by glasses. She has some scars of upper part of cornea simulating those found in trachoma, with slight pannus. I was surprised on everting the lid to find no indication of her ever having had trachoma. Vision right eye  $\frac{2}{300}$ , and eccentric. She said her right eye had been blind (following a spell of sickness) since she was 15 years old, or twenty-seven years. She did not come to consult me concerning her right eye, yet as a matter of routine I examined it. I found all the media perfectly clear. Just at or over right macula I discovered a sac or cyst, pedunculated, the pedicle being attached to the retina above and external to the macula, the body of the sac

extending down and in over the region of the macula. The sac with its pedicle appeared a bluish gray and opaque, except a part of the wall toward me about the size and shape of the optic nerve entrance, which was transparent and through which the deeper or other wall could be seen. The eye was emmetropic with the ophthalmoscope. The highest or most prominent part of the sac, just at the transparent part referred to, could be seen best with a + 10 D., showing an elevation of about 2.3 mm. The other cyst wall could be seen through this transparent portion best with about a + 2 D., showing an elevation of about 0.52 mm. The sac was ovoid in shape with the edges at some points serrated, and at one point down and in there was quite a projection. Over this sac small blood vessels could be seen, one up and in could be traced to a large retinal vessel close by. No motion could be discovered in this opaque cyst. Forming something of a crescent from the lower and outer part of this sac was a transparent, reddish cyst; at the upper part of this cyst could be seen two spots looking like air bubbles, which were no doubt the parasite's suckers. This cyst when watched closely could be seen to have a distinct rhythmical motion; a spot of pigment beneath it would appear and disappear; the motion was perfect. Above the attachment of the pedicle of the cyst could be seen two white, crescent-shaped spots, no doubt the points of entrance of the parasite. The retina between the cyst and optic nerve presented the appearance of a recent detachment. Several large vessels ran from the nerve direct to the sac, some of them disappearing under it and reappearing on the other side. There were many more large vessels taking this course than usual. This would probably indicate that the trouble is of long standing. The vitreous seemed to be detached over the optic nerve entrance. I called Drs. Dabney and Pusey, of this city, to see the case, on account of its rarity and interest, and to confirm my diagnosis, which they both did.

Mrs. F. gives a history of several serious attacks of what she called congestion of heart and lungs, several years ago. For six or seven years up to January last, when her left eye was so badly inflamed, her health had been very good. She thinks she is going through her "change." Left eye usually inflamed some every four weeks. This case, besides being the second, so far as I know of, reported in America, presents other points of interest. Could this parasite possibly have been the original cause of the loss of vision of right eye twenty-seven years ago? I think this possible and quite probable. The vitreous is clear and but little damaged, but a small part of the retina and choroid are damaged. The parasite, from the appearance of the parts, seems to have left its old bed, and is migrating. Mrs. F. does not remember of ever having had any pain in her right eye. Could the disease she has had in her left eye be sympathetic? Sympathetic affections have their exacerbations and their times of quiet, as we all know.

Foster, Encyclopedic Medical Dictionary, page 1237, says:

*Cysticercus cellulosus* is the larval stage of *tænia solium*. It has a quadrangular head, a long cylindrical body, and an elliptical, caudal vesicle, and is from 10 to 15 mm. in length.

Manthuer describes the animal as follows:

The worm is provided at its posterior end with a round cyst-like formation which acts as the receptaculum scolice, into which the animal can withdraw, presenting when in this position the appearance of a round, whitish body. A small hole marks the mouth of this small receptacle. When the animal protrudes its head and neck out of the receptacle its body appears to be sprinkled here and there with calcareous deposits, and presents sometimes a smooth and sometimes a wrinkled surface. The body decreases in size toward the neck, to which is attached the head, with its four flattened down but angular projections. A round-shaped snout can be projected by the animal from the center of its head, and this latter is provided at its base with a double row of hook-like tentacles, which are capable of retraction. Each of the angular projections of the head is, moreover, provided with a rounded sucking apparatus.

Schmidt-Rimpler, page 276, says:

The embryo enters the stomach of the suitable host in the food or water, loses its covering through the action of the gastric juice, bores into the blood vessels with its hooks, and begins to wander. Finally it becomes settled, and now begins the second stage of its development in which it is known as *cysticercus*. It is converted into a vesicle with fluid contents. All authors agree that the embryo travels by the blood current. *Cysticerci* may occur in any part of the eye or orbit. They have been seen in the orbit, lids, conjunctiva, iris, lens, vitreous, choroid, and retina. They are found more often in the posterior part of the eyeball than in the

anterior. They are quite common in Northern Germany, where uncooked meats are eaten; less often in Southern Germany, France, and Italy. There have been three cases reported in Austria. Brudenell Carter says none have been seen in England, but Soelberg Wells reports a case in his book, page 328. In Northern Germany, Graefe saw 80 cases in 80,000 patients, or 1 in 1,000 in the deeper tissues of the eye, 3 in the anterior chamber, 5 beneath the conjunctiva, and 1 in the orbit. Hirschberg in six months saw 2,100 new patients, in 5 of which he saw cysticercus, or 1 in 420 cases of eye diseases.

Of the one other case seen in this country, reported by Dr. Minor, Loring, on page 188, says:

From the ophthalmoscopic appearances there was reason to believe that it was a true case of cysticercus, although it was not absolutely proved to be so.

Yet, from Dr. Minor's description of the case and the ophthalmoscopic appearances (page 193, Loring), I do not think there can be any doubt of its having been a case of cysticercus cellulosæ. How long a cysticercus can remain in an eye is in doubt. Cases of two and four years' standing are common. Von Graefe saw a case in 1856, which was twenty years afterwards seen intact by Hirschberg. Others have reported cases of long standing with vision nearly perfect. My case, as I stated before, is possibly of twenty-seven years' standing. Usually, though, in from fifteen to twenty months, irido-cyclo-choroiditis follows, and sometimes panophthalmitis, with total loss of the eye. Von Graefe and Hirschberg state that there is not much danger of sympathetic inflammation, although sympathetic irritation is often present. Jacobson reports sympathetic amblyopia. Two cysts have been seen in one eye, but no case has been reported of both eyes being involved. Patients with cysticercus do not have tape-worm. The presence of this parasite in the eye is so dangerous to the vitality and the usefulness of the organ that its removal has been undertaken and with success, but not with very flattering after results when it is located in the posterior part of the organ. When in the iris a section of this membrane that holds the parasite can be removed.

#### RELACIONES DE LA OFTALMOMETRÍA CON LA SKIASCOPIA.

Por el Doctor PEDRO LAGLEYZE,

*Profesor de Oftalmología en la Facultad de Buenos Aires.*

Kohlrausch, en 1839, propuso determinar el sitio del astigmatismo mediante las medidas comparativas de las imágenes reflejadas por la córnea. Senff, en 1846, emprendió este estudio, pero es en realidad Helmholtz quien, en 1854, demostró la importancia de este método midiendo las curvaturas de la córnea y del cristalino.

El oftalmómetro de Helmholtz, precioso instrumento matemático para las medidas fisiológicas, no es aplicable en la práctica diaria de la clínica. Javal y Schiötz, en 1881, construyeron un aparato basado sobre los mismos principios, adaptándolo a la clínica por un fácil manejo y haciendo innecesarios los cálculos matemáticos que exige el oftalmómetro de Helmholtz.

La oftalmometría descubre astigmatismos que escapan al más prolijo exámen por los métodos ordinarios, y cuando se ha usado durante algun tiempo el oftalmómetro de Javal, es difícil hacer optometría sin este precioso instrumento, que sin titubear, y con gran exactitud nos indica el rayo de curvatura de los meridianos principales de un astigmatismo en menos de un minuto.

Este instrumento es casi imprescindible para el clínico, pues sin él, no es posible descubrir en el astigmatismo total, la parte de refracción astigmática, dinámica ó estática, que pueda corresponder al cristalino; cuestion importante para la prescripción de lentes.

Cuando el astigmatismo total sea igual al córneo, no debe titubearse en indicar el cilindro que haga la corrección total. Si el astigmatismo total es mayor que el de la córnea, deberá tenerse en cuenta para la prescripción del cilindro no solamente la

relación entre la diferencia refringente, sino también la dirección del meridiano córneo de menor rayo con la dirección del astigmatismo total.

De igual modo se procederá cuando el astigmatismo total sea menor que el indicado por el oftalmómetro. Débese siempre buscar con cuidado si estas diferencias son debidas á contracciones parciales del músculo ciliar, y guiarse para la corrección de tal manera que el vidrio no sea causa de que esta contracción irregular se mantenga, debiendo, por el contrario, dirigir todos los esfuerzos á fin de que desaparezca.

Cuando estas diferencias sean pronunciadas y principalmente si la mayor refringencia tiene lugar sobre el meridiano horizontal, será conveniente medir la refracción total bajo la acción atropínica y comparar el resultado.

Algunos autores sostienen que los resultados obtenidos por el oftalmómetro de Javal y Schiötz señalan vidrios superiores al examen subjetivo. Oswalt es uno de los que sostienen esta tesis, pero su trabajo carece de valor porque no se basa en la práctica y porque parte de una premisa falsa sobre el valor dióptrico del ojo. Los doctores Motais, Pflatz y G. J. Bull dicen igualmente que en la gran mayoría los pacientes no admiten el cilindro indicado por el oftalmómetro, sino solamente un cilindro más débil. Story dice que los vidrios indicados por el oftalmómetro son media dióptria más fuertes que el astigmatismo subjetivo. Chibret sostiene lo contrario diciendo que, según sus trabajos de control por la skiascopia, el oftalmómetro da numeros menores en lugar de aumentarlos. Tscherning y Javal han demostrado, el primero científicamente y el segundo por la clínica, que en los fuertes grados el astigmatismo subjetivo es generalmente superior al indicado por el oftalmómetro.

No se pueden hacer conclusiones generales sin indicar la dirección de máxima curvatura de la córnea, pues el astigmatismo total varía según esta inclinación. Javal ha estudiado desde 1880 hasta el año 1887 las relaciones que existen entre el astigmatismo total y el astigmatismo de la córnea, habiendo llegado á las siguientes conclusiones:

El astigmatismo regular comprende á lo menos tres especies distintas.

Una de ellas se presenta en general en los ojos cuyo meridiano vertical presenta la mayor curvatura. La segunda se encuentra habitualmente en aquellos en que el astigmatismo está colocado en una dirección perpendicular á la del caso precedente.

En fin, la tercera variedad se encuentra más amenudo en los ojos en que los meridianos están situados en 45 grados.

En la primera de estas variedades, la más ordinaria, la totalidad del achaque reside en la córnea, ó sea el astigmatismo total difiere poco del astigmatismo córneo.

En la segunda, la deformidad reside principalmente en el cristalino, de tal manera que el astigmatismo total es superior al astigmatismo córneo.

Desde luego, cuando tengais que dar vidrios á enfermos de esta categoría, no debeis sorprenderos de encontrar amenudo una ó dos dióptrias de astigmatismo cristalino estático.

Es entre los ojos de esta categoría que se reclutan en masa el glaucoma y la catarata.

La tercera variedad que se encuentra más amenudo en los ojos cuyos meridianos forman ángulos de 45° con la vertical, no se asemeja á las precedentes. Se acompaña de una descentración del globo que puede llegar hasta 20 y 25°. Aquí los vidrios correctores no corrijen sino mediante una visión oblicua. (Soc. franç. d'opht. Congr. de 1887. Sess. 2 mai.)

Swan Burnet dice que el oftalmómetro da cifras mayores para el astigmatismo según la regla y más débiles para el contrario á la regla, creyendo que esto último es debido á una inclinación del cristalino. El error en ambos casos, dice, que es de 0.50 D. y que una diferencia mayor entre el examen oftalmométrico y el subjetivo indica la instilación de un midriático para deslindar las contracciones parciales del músculo ciliar del astigmatismo estático. (Washington, Congr. Soc. médica americana, Mayo, 1891.)

La corrección útilmente aplicable al astigmatismo está generalmente comprendida entre las indicaciones oftalmométricas y skiascópicas. El resultado subjetivo se acercará lo más amenudo al astigmatismo oftalmométrico en los casos de astigmatismo según la regla, y al astigmatismo skiascópico en los casos que el astigmatismo sea contra la regla.

No debe pedirse al oftalmómetro más de lo que puede dar. Si el vidrio se llevara pegado sobre la córnea, y si no se tuviera en cuenta al agente cristaliniano, que en general no altera en mucho el resultado, el oftalmómetro indicaría la prescripción del vidrio. Pero no debe olvidarse lo que para muchos observadores ha pasado sin importancia, que el oftalmómetro indica el astigmatismo córneo y no el vidrio corrector; para hallar su justo valor es necesario tener en cuenta la distancia que separa al antejo de la córnea. Esta distancia negligible para los débiles grados, y en general para los astigmatismos simples, debe de tenerse muy en cuenta para los astigmatismos compuestos.

Esta es una de las causas que debe señalarse como una de las más frecuentes y poderosas en las diferencias del astigmatismo total y córneo.

A continuación presento una serie de cuadros comparativos que demuestran las diferencias indicadas entre el exámen oftalmométrico y skiascópico, correspondientes á cada grupo, y ordenados según la variedad del astigmatismo y la dirección del meridiano más refringente.

Los signos (+) y (—) indican la relación del meridiano más refringente entre las medidas encontradas por el oftalmómetro y la skiascopia. El signo (+) señala el exceso oftalmométrico sobre el skiascópico, y el signo (—) el de la skiascopia sobre el oftalmómetro.

Este trabajo se basa sobre el estudio analítico de 1,230 ojos examinados durante el año 1891. En todos he medido la refracción total por medio de la skiascopia, y el rayo de curvatura de la córnea con el oftalmómetro de Javal y Schiötz.

El aparato que he usado para la medida de la córnea es el ejemplar No. 123, construido por A. Goubeaux, con las últimas modificaciones de Javal, es decir, con el raro grado de perfección que posee desde el año 1889.

*Diferencia entre el astigmatismo indicado por el oftalmómetro y la skiascopia.*

EL OFTALMÓMETRO Y LA SKIASCOPIA NO REVELAN ASTIGMATISMO EN 153 OJOS AMETRÓPICOS.

Lo que más resalta en estos cuadros es que el valor del astigmatismo indicado por la skiascopia prevalece sobre el valor refringente correspondiente á la medida de la córnea, principal sitio del astigmatismo.

El cuadro que sigue demuestra el término medio para cada variedad de astigmatismo. Todos representan una cantidad negativa para el oftalmómetro con excepción del último grupo, en el cual el astigmatismo córneo se halla corregido por un astigmatismo inverso del cristalino, ocultándolo por completo.

*Relación media entre la oftalmometría y la skiascopia según la variedad del astigmatismo y la dirección del meridiano más refringente.*

| Horizontal .....           | 10              | +0.57     |

El estudio de este cuadro demuestra que cada grupo presenta sus meridianos oscilando próximamente al rededor de una misma cifra. El meridiano oblicuo del astigmatismo mixto hace excepción á esta regla general.

Dice Javal que cuando subjetivamente existe astigmatismo y el oftalmómetro no lo revela, el astigmatismo es contrario á la regla. Mis resultados no están contestes con los de Javal. Tanto el meridiano horizontal como el vertical se hallan casi en

igual número en ojos miopes como en hipermétropes; el meridiano oblicuo solo en muy pequeño número de miopes y en ningún hipermetrope.

He aquí, para cada grupo, el valor medio de las diferencias entre las medidas oftalmométricas y skiascópicas:

|                                            | No. de ojos. | Média.             |
|--------------------------------------------|--------------|--------------------|
| Astigmatismo miópico simple.....           | 129          | <i>D.</i><br>—0.18 |
| Astigmatismo miópico compuesto.....        | 315          | —0.60              |
| Astigmatismo hipermetrópico simple.....    | 120          | —0.02              |
| Astigmatismo hipermetrópico compuesto..... | 199          | —0.09              |
| Astigmatismo mixto.....                    | 106          | —0.72              |

El oftalmómetro no indica astigmatismo y la skiascopia sí, en 37 ojos; media —0.96 D.

El oftalmómetro indica astigmatismo y la skiascopia, no en 171 ojos; media +0.44 D.

Los valores de la diferencia media según la inclinación del meridiano más refringente, incluyendo todas las variedades del astigmatismo, son:

|                                                              | <i>D.</i> |
|--------------------------------------------------------------|-----------|
| En 806 ojos con el meridiano vertical más refringente.....   | —0.28     |
| En 108 ojos con el meridiano oblicuo más refringente.....    | —0.12     |
| En 163 ojos con el meridiano horizontal más refringente..... | —0.35     |

Si de los 1,230 ojos descontamos 153 ametrópicos, en los cuales el oftalmómetro y la skiascopia no han revelado astigmatismo, tendremos 1,077 ojos de un astigmatismo próximamente de 0.25 D. no verificado por el oftalmómetro.

*Proporción centesimal del número de astigmáticos según su variedad y meridiano de mayor refringencia en el astigmatismo total.*

|                                                                              | Vertical. | Oblicuo. | Horizontal. | Total. |
|------------------------------------------------------------------------------|-----------|----------|-------------|--------|
| Astigmatismos indicados por el oftalmómetro y la skiascopia en el meridiano: |           |          |             |        |

| Astigmatismos no indicados por el oftalmómetro y sí, por la skiascopia:      |           |          |             |        |
| Astigmatismos hipermetrópicos.....                                           | 0.84      | .....    | 0.74        | 1.58   |
| Astigmatismos miópicos.....                                                  | 0.84      | 0.28     | 0.74        | 1.86   |
| Astigmatismos indicados por el oftalmómetro y no por la skiascopia:          |           |          |             |        |
| Astigmatismos hipermetrópicos.....                                           | 8.08      | 0.46     | 0.74        | 9.28   |
| Astigmatismos miópicos.....                                                  | 4.64      | 1.02     | 0.93        | 6.59   |
| Total.....                                                                   | 74.84     | 10.03    | 15.13       | 100.00 |

Estos números comparativos han sido deducidos de una cantidad de 1,077 astigmáticos totales, ellos demuestran proporcionalmente sobre cada cien casos, la relación de las diversas variedades de astigmatismos y de la inclinación de los meridianos de mayor refringencia.

Las cifras de este cuadro conducen á las siguientes conclusiones:

1ª. Las sumas de astigmatismos simples descubiertos por el oftalmómetro y la skiascopia, revelan entre sí una diferencia tan pequeña que, sin gran error, pueden considerarse iguales.

Descomponiendo el astigmatismo simple según los meridianos de mayor refringencia, tendremos:

(a) El meridiano vertical presenta un número igual de astigmatismos simples hipermetrópicos y miópicos;

(b) El meridiano oblicuo se manifiesta en una justa é igual cantidad;

(c) El meridiano horizontal acusa una notable diferencia en favor del astigmatismo miópico simple, siendo casi dos veces más numeroso que el astigmatismo hipermetrópico simple;

(d) Las sumas del astigmatismo hipermetrópico y miópico simple en sus meridianos oblicuos, lo mismo que en el horizontal, se presentan en igual número de casos, siendo la suma del meridiano vertical de ámbos astigmatismos simples ocho veces más frecuente que la suma de cada uno de los otros dos meridianos.

2ª. Las sumas de astigmatismos compuestos, indicados por el oftalmómetro y la skiascopia, se hallan en la proporción de cien astigmatismos miópicos compuestos para cada 63 astigmatismos hipermetrópicos.

Los meridianos del astigmatismo compuesto entre los miópicos é hipermetrópicos, se encuentran en la siguiente proporción:

(a) El meridiano vertical prepondera en los miópicos, siendo de casi  $\frac{3}{2}$  la proporción de astigmatismos miópicos compuestos con relación á los hipermetrópicos;

(b) El meridiano oblicuo ligeramente superior para los miópicos da más ó menos  $\frac{9}{8}$  en la proporción con los hipermetrópicos, exceso que puede negligirse aceptando como conclusión: igual número de astigmatismos compuestos miópicos é hipermetrópicos para el meridiano oblicuo;

(c) El meridiano horizontal tiene en el astigmatismo compuesto una diferencia más notable que la indicada por el astigmatismo simple, siendo tres veces más frecuente en el astigmatismo miópico compuesto que en el hipermetrópico;

(d) La relación de los meridianos según su inclinación no es igualmente proporcionada en el astigmatismo miópico compuesto que en el hipermetrópico. El meridiano vertical del astigmatismo miópico compuesto es poco más de siete veces más frecuente que el oblicuo, y solo tres veces más frecuente que el horizontal. El meridiano vertical del astigmatismo hipermetrópico compuesto es seis veces más numeroso que el oblicuo y también que el horizontal;

(e) Las sumas de los meridianos correspondientes del astigmatismo miópico compuesto é hipermetrópico da para el meridiano vertical una frecuencia dos veces y media mayor que los otros dos meridianos juntos. Siendo el meridiano vertical casi siete veces más numeroso que el oblicuo, y cuatro más que el horizontal.

3ª. El astigmatismo mixto, descubierto por el exámen oftalmométrico y skiascópico ha revelado que el meridiano vertical más refringente se presenta siete veces y media más frecuentemente que cada uno de los otros meridianos, hallándose los meridianos oblicuo y horizontal en igual número de casos.

4ª. El oftalmómetro no ha revelado astigmatismo mientras que la skiascopia ha indicado asimetría en la refracción ocular, provocada por el cristalino solamente, en un caso para cada 29 astigmatismos:

(a) La cantidad de astigmatismos hipermetrópicos, pueden considerarse como igual á la de astigmatismos miópicos indicados por la skiascopia y no por el oftalmómetro.

(b) El meridiano vertical se ha presentado igual número de veces en los ojos hipermetropes y miopes, lo mismo ha sucedido con el horizontal.

(c) El meridiano oblicuo no se ha manifestado en ningún astigmatismo hipermetrópico, y tan rara vez en ojos miopes (1 por 359 astigm.), que puede darse como regla general la falta de astigmatismo cristalino en los meridianos oblicuos.

(d) El meridiano vertical es  $\frac{2}{3}$  veces más frecuente que el horizontal.

5ª. El oftalmómetro ha indicado sin que la skiascopia revele astigmatismo un número de ojos cuatro y media veces mayor que en el caso anterior. La skiascopia no descubre la asimetría porque el astigmatismo córneo se halla corregido por un astigmatismo inverso del cristalino:

(a) La cantidad de astigmatismos hipermetrópicos es de  $\frac{1}{3}$  con relación al número de astigmatismos miópicos.

(b) El meridiano vertical más refringente se presenta en mayor número en los astigmatismos hipermetrópicos, siendo casi el doble de los miópicos.

(c) El meridiano oblicuo es la mitad menos frecuente en los hipermetrópicos.

(d) El meridiano horizontal se presenta en los  $\frac{4}{5}$  de hipermetrópicos con relación al mismo meridiano en los miópicos.

6ª. La relación de los meridianos entre sí, de la suma total de todos los astigmatismos clasificados en el cuadro centesimal, es:

|                                   |       |
|-----------------------------------|-------|
| Para el meridiano vertical .....  | 74.84 |
| Para el meridiano oblicuo.....    | 10.03 |
| Para el meridiano horizontal..... | 15.13 |

De tal manera, que el astigmatismo según la regla, es decir el vertical, es siete veces y media más frecuente que el oblicuo, y cinco veces más que el llamado contrario á la regla, ó sea el horizontal, siendo este último una vez y media más frecuente que el oblicuo.

---

### ADDRESS BY THE PRESIDENT OF THE SECTION, E. FLETCHER INGALS, A. M., M. D.

GENTLEMEN AND COLLEAGUES : In calling to order the laryngological section of the Pan-American Medical Congress I take the opportunity to congratulate you upon the number and excellence of the papers which have been secured for your consideration. I feel that there is a special reason for felicitation upon the propitious circumstances under which we have convened, because of our success in spite of many obstacles. The laryngologists of this country, as well as those who would have visited us from abroad, have been called upon for more than the usual amount of work during the past few months. Early in May the American Laryngological Association met in New York and was largely participated in by those who other-

wise would have been free to aid us. Shortly afterwards the American Climatological Association met in Philadelphia, taxing the energy and taking the time of many of the laryngologists of this country. And only three weeks subsequently the American Medical Association met in Milwaukee, with a large attendance upon the laryngological section. In addition to these, the various State medical societies called out a considerable number of papers upon diseases of the throat and nose. Besides this, many laryngologists who contemplate going abroad have undertaken to prepare papers for the International Medical Congress, which was to have met in Rome shortly after the close of this congress.

When the American Laryngological Association held its first annual meeting in 1879 there were, all told, less than thirty men in the United States sufficiently interested in the subject to be counted laryngologists. But the ranks have been added to rapidly year by year, until now there are probably not less than four times that number who are well equipped; and in all of the cities and larger towns throughout the country are others more or less qualified who are doing considerable work in this special line, and it is probable that to-day 500 men could be found in the United States who might present something of interest to this body, though I have been able to discover only about 200 of them.

Nearly a year ago I opened correspondence with the physicians of Central and South America and the West Indies, hoping to get them to join us in this congress, but I regret to say that in only a few instances have I been able to obtain replies to my letters, and that only two or three of our colleagues in those countries have promised papers for this occasion. Considering the limited intercourse which has always existed between the United States and the Latin Americas, this is not a matter of surprise, but it is hoped that this congress will be a beginning of a closer alliance and personal friendships, which will, in coming years, bring us often together, and build up a powerful International Congress in this Western Hemisphere.

The railroad already projected through Central America, which will connect with various railroad systems in South America, and increased means of communication by sea, will, it is believed, ere long, open up to the physicians of the United States many new and valuable resorts whose climatic influences may be made subservient to our patients in their search for health. When this has been brought about it is obvious that our acquaintance with the physicians in these southern climes will be of the greatest advantage to our patrons.

We welcome you one and all to our national capital. We ask of each your hearty coöperation in the work before us, and we believe the final results will justify the large amount of labor and anxiety which have been expended in this undertaking.

## PAPERS READ BEFORE THE SECTION.

## REFLEX EPILEPSY FROM INTRA-NASAL DISEASE.

By JOHN O. ROE, M. D., of Rochester, N. Y.

The existence of reflex neuroses has been known since the earliest period of medical history. In an excellent historical study on this subject, read before the American Laryngological Association in 1887, Mackenzie<sup>1</sup> traces the general history of such neuroses from the time of Plato and Aristotle to that of Bostock, in the second decade of this century. Of the neuroses that may be excited by peripheral irritation probably epilepsy is the most important; for, as Watson<sup>2</sup> very truly says:

While it is a disease probably not painful in itself, seldom immediately fatal, often recovered from altogether, it is yet apt, in many cases, to end in fatuity or insanity, and carries perpetual anxiety and misery into those families which it has once visited.

It was called the "sacred" disease by the ancients—"either," as Aretæus<sup>3</sup> says, "from its magnitude (for what is great is sacred) or from the cure not being in the power of man, but of God, or from the notion that a demon has entered the patient, or from all put together."

The earliest conception of the malady was that it is a disease of the brain, and incurable. Aretæus seems, however, to have recognized that the exciting cause may reside in other parts, for he says:

Occasionally the malady is fixed in the head, and that is the starting point of the paroxysms; in other cases it begins in the nerves which are most remote from the head and which sympathize with the part affected.

The nose seems to have been the part of the body which was first recognized to be so vulnerable to external influences as to excite epileptic attacks. Mackenzie<sup>4</sup> says that among the older writers many cases are recorded in which the odor of various substances was known to result in epilepsy; and Salmuth,<sup>5</sup> in 1648, called attention to the fact that paroxysms of epilepsy are often relieved by the eruption of blood from the nose. Since that time, irritation of nearly every part of the body has been observed to be the cause of epileptic convulsions. The first scientific light was thrown upon this subject about forty years ago by Brown-Séquard,<sup>6</sup> who showed by a series of carefully conducted experiments on animals that epilepsy could be produced by the artificial irritation of the peripheral nerves in almost any part of the body. The first experimenter, however, to formulate a distinct physiological theory of epilepsy was Marshall Hall.<sup>7</sup>

According to Marshall Hall the seat of epilepsy is in the medulla oblongata. To fully understand his system one must remember that this medulla oblongata, the seat of reflex or excito-motor movements, has the power of receiving impressions conveyed by the sensory nerves, which act as centripetal conductors, and also possesses the power of transferring them to the muscular system by the

<sup>7</sup>See T. Falret, Théories Physiologiques de l'Épilepsie; in Archives général de Médecine, February to May, 1862.

motor nerves, which act as centrifugal conductors. If the medulla oblongata, being morbidly excited, experiences a stimulus either from the brain or periphery, such stimulus will be abnormally transmitted to the muscular system, and reflex movements of greater or less irregularity and violence will be produced.

Brown-Séguard accepted Marshall Hall's theory in general, and developed it with remarkable ability in a large number of papers. Accordingly it was generally received until 1870, when the question assumed another aspect.

It was in that year that Fritsch and Hitzig<sup>1</sup> published their first researches upon the motor centers of the brain. By them it was demonstrated that mechanical irritation of certain regions of the cerebral cortex caused convulsions similar to those of epilepsy. Hitherto the most eminent physiologists had unanimously held that the brain was functionally homogeneous, and that stimulation of neither surface nor deeper parts would be followed by any motor reaction. The observations of Fritsch and Hitzig were, however, soon confirmed by a large number of experimenters. Without depriving the medulla oblongata of the function attributed to it by Marshall Hall and Brown-Séguard, it is thus clearly established that it has not the exclusive power of provoking epileptic convulsions. Thus we immediately have the question brought before us, Is there a difference between convulsions of cortical origin and medullary origin, and why are sometimes the former, sometimes the latter, produced? It is this question that Hughlings Jackson<sup>2</sup> endeavors to answer in the Lumleian Lectures for the year 1890. According to Jackson the central nervous system is composed of three superimposed levels, representing degrees of evolution more and more advanced. In each of these levels, the lower, middle, and upper, there is a set of cerebral convolutions. The lower level consists of the spinal cord, the medulla, and pons, and represents the simplest movements of all parts of the body. The middle level of the cerebral system is composed of centers in the Rolandic region (so-called "motor region" of the cerebral cortex), and possibly of the ganglia of the corpus striatum also. It represents complex movements of all parts of the body from eyes to perineum.

The upper level of the cerebral system is made up of centers of the prefrontal lobes. This represents the most complex movements of all parts of the body and presides over "epilepsy," properly so called. These three levels are all sensorimotor, and in each of them convulsions are produced by the same mechanism. To these anatomical classifications there is a corresponding classification of convulsions. These convulsions constitute genuine epilepsy only when they are of cerebral origin; that is, when they originate in the highest level; otherwise minor convulsive movements are manifested, such as petit mal. In order to explain the mechanism of the convulsion, Hughlings Jackson adopts Schroeder van der Kolck's<sup>3</sup> idea of comparing the nerve center to a Leyden jar, the convulsion to the discharge of the jar. He starts with this principle—that all nervous phenomena are to be traced to a nervous discharge, or liberation of the energy of the nervous elements. This discharge takes place in all healthy operations. When produced abnormally there results a discharge by explosion, and as a result convulsive movements of certain portions of the body that are in direct connection with the portion of the cortex irritated. Hence this form of epileptic manifestations, or hemi-epilepsy, has been distinctly characterized as "Jacksonian epilepsy." The irritation in this case may be applied to the brain center itself, or may be reflected to it from some distant part. Hughlings Jackson goes so far as to say that there is "in every case of epileptic seizure a persistent discharging lesion," and that he would advise cutting out that lesion, whether it was produced by tumor or not.

<sup>1</sup> Reichert and Du Bois-Raymond's Archiv, 1870, No. 3.

<sup>2</sup> British Medical Journal, 1890, Vol. I, p. 703.

<sup>3</sup> On the Minute Structure and Functions of the Spinal Cord, etc.; translated by W. D. Moore. London, New Syd. Soc., 1859.

Hughlings Jackson's theory of cortical irritation has since been fully sustained by the brilliant achievements in brain surgery of Victor Horsley and Schäfer,<sup>1</sup> Mac-ewen,<sup>2</sup> Ferrier,<sup>3</sup> Keen,<sup>4</sup> Lloyd and Deaver,<sup>5</sup> Mills,<sup>6</sup> Leo.<sup>7</sup> Bennett and Gould,<sup>8</sup> Barker,<sup>9</sup> Park,<sup>10</sup> Oliver,<sup>11</sup> Seguin and Weir,<sup>12</sup> and Harrison.<sup>13</sup>

As the most usual peripheral causes that may excite cortical irritation, manifested in epilepsy, may be mentioned diseases of the ear, teeth, eyes, uterine appendages, and the nose. Disease of the external or middle ear may in some cases be associated with reflex epilepsy, entirely independent of any direct involvement of the brain itself. Moos<sup>14</sup> reports a case of middle-ear disease which resulted in epileptic seizures. A large number of similar instances are recorded elsewhere by various writers. Elaborate researches on the relation of epilepsy to ear disease, when the disease acts as a causative factor, have been made by Boucheron<sup>15</sup> and Ormerod.<sup>16</sup> Ormerod tested the ears of 200 epileptic patients, and found that 31 of them had a previous history of suppurative otitis, past or present. As a counterstudy, 100 patients with ear disease were examined for epilepsy. Seven cases were found. Brubaker<sup>17</sup> has reported 16 cases of epilepsy due entirely to the presence of decayed teeth, and an interesting instance has also been reported by Schwartzkopff.<sup>18</sup> Other references to similar cases are given by Hare.<sup>19</sup>

G. Sous<sup>20</sup> reports a case in which relief from epileptic convulsions was obtained by the removal of a cataract, and Galezowski<sup>21</sup> records a case of epilepsy that was due to the reflex irritation produced by inflammation of the stump of an optic nerve after the eye had been removed. In 1876 Stevens,<sup>22</sup> of Albany, N. Y., said that in 70 cases of epilepsy examined by him only 3 were free from refractive lesions, and in 2 of these deep excavation of the optic nerve existed, a condition liable to give rise to a most troublesome form of asthenopia. At the same time he presented a table showing the refractive condition of the eyes in 54 cases of epileptic insane persons and in only a very small proportion of these cases was the vision normal.

As far back as 1698 Eickmeyer<sup>23</sup> published a work on uterine epilepsy, and two quartos appeared in 1764 on the same subject, one by Poley<sup>24</sup> and the other by Schneider.<sup>25</sup> In 1859 Eagon<sup>26</sup> reported a case of epilepsy succeeding the suppression

of the menstrual discharge and cured by the restoration of the catamenia. Curran<sup>1</sup> and Terrillon<sup>2</sup> have each recorded notes of cases of uterine epilepsy, and Thomas<sup>3</sup> has described a case of ovarian origin. In the instance mentioned by Engelmann<sup>4</sup> the epilepsy was dependent upon erosions of the cervix uteri, and the convulsions described by Carstens<sup>5</sup> were due to uterine stenosis.

Of instances of epilepsy whose origin may be traced to intra-nasal disease, 3 cases have been reported by De Vilbis.<sup>6</sup> In each of these cases the epilepsy was the result of so-called "nasal catarrh." Fincke<sup>7</sup> gives a full and very interesting report of a case in which the removal of nasal polyps gave complete relief from epileptic attacks, and Schneider<sup>8</sup> has cured 6 cases of epilepsy by the treatment of nasal disease. In some of the instances mentioned by Schneider, the epilepsy was complicated with attacks of asthma; in others there were no complications of any nature. Erlenmeyer<sup>9</sup> reports the case of a physician, 25 years old, who had an attack of influenza. About a month later he suffered from epileptiform convulsions, which Erlenmeyer believed to have resulted directly from the attack of influenza. Abramson<sup>10</sup> cured a girl who was suffering from nightly epileptic attacks by cauterization of hypertrophic rhinitis and enlargement of the turbinated bodies. Two cases of a similar nature are reported by Crossfield.<sup>11</sup> Griffin<sup>12</sup> removed a shoe button from the left nostril of a young girl suffering from epileptic convulsions, thus affording her instant relief. The button had become incrustated with the saline portions of the serum, and formed the nucleus of a rhinolith. The calculus was the size of a hazelnut. No medicine whatever was administered, nor were there any recurrences of the convulsions. Hinsdale<sup>13</sup> reports a case, given to him by Dr. Weir Mitchell, in which epilepsy was cured by the removal of a bean from the nose of the patient. In each of 2 cases observed by me and herewith reported, the epilepsy was the result of turbinated exostosis and hypertrophy, causing pressure on the septum.

*Case 1.*—Miss M., aged 23, was brought to me by her family physician, Dr. Townsend, of Bergen, N. Y., July 30, 1889. Her case presented the following history: One morning in February, 1888, she was found just recovering from a convulsive attack. Dr. Townsend was immediately summoned. As no one was present at the time when she was supposed to have fainted, the nature of the attack could not be made out. She was then well-nourished, had good color; all her functions, so far as could be ascertained, were normal. Suspecting that Miss M. had had a convulsion, Dr. Townsend instructed her parents to watch her closely. After the girl had three similar attacks alone, the fourth attack was observed by her mother, who described to the doctor the phenomena so well that there remained no doubt in his mind as to the true nature of the malady. It appeared that the patient was aware for many minutes previous that an attack was coming on, and could call her mother, who, in this instance, reached her before any convulsive effort had taken place. From March, 1888, to January, 1889, her attacks increased in frequency, from one in two weeks to two and sometimes three a week. On considering the long interval of consciousness after an attack was felt to be coming on before the stage of rigidity and unconsciousness occurred, the doctor thought that the case might be one of focal epilepsy. He finally took her to an oculist for an examination into the condition of her eyes, but nothing abnormal was detected

in the examination. The doctor then took her to his own residence, and as the attacks nearly always occurred at night, after one nap, he had her sleep in an adjoining room. About five minutes before the attack she would call him, and having time to dress himself partly, he would go almost immediately to her. At no time during nearly two months and a dozen seizures could he discover any rigidity of any muscles or set of muscles, fingers or toes, in advance of the general muscular convulsion. He, therefore, gave up the supposition that it was a case of Jacksonian epilepsy. The case was, therefore, unquestionably one of typical epilepsy, and it was attended by nearly all the customary phenomena. There were convulsive movements of all the muscles, frothing at the mouth, biting of the tongue, and a period of unconsciousness, followed by a condition of languor.

A complete history of the patient was gone into by the doctor. He found that she had experienced two falls, one from a horse and one from a step-ladder. He could not learn, however, that there was any interval of unconsciousness after either, nor could he discover any mark or asymmetry of the cranium, nor that she had any disease or lesions about her, with one exception—she had suffered from nasal catarrh for quite a long time, and there was obstruction to nasal respiration. For the purpose of investigating the latter condition, the doctor brought her to me for an examination. There was found considerable inferior turbinated hypertrophy on both sides, and in the right nostril there was an exostosis of the middle turbinated bone which pressed firmly against the septum. Pressure against this region with the probe produced the sensations which she experienced just previous to the occurrence of an epileptic convulsion. The nasal obstructions were, therefore, removed, together with the exostosis in the middle turbinated bone.

For some time previous to the date when I saw her she had become very restless, and had much mental depression, particularly for a time after each attack. This condition speedily disappeared after the removal of the intranasal abnormality, and she has had no attack of epilepsy since. That this improvement is due solely to the operation in the nose, both Dr. Townsend and myself unqualifiedly believe, for the reason, as he states, that the patient had not taken for months before the operation, nor has she taken since, any medical or other treatment, except an antiseptic solution that I gave her to be used in an atomizer for spraying and cleaning the nose for a time after the operation.

*Case 2.*—Master A. B., aged 14, was referred to me September 16, 1891, on account of a persistent headache, associated with more or less nasal obstruction, attended with frequent convulsive attacks, the nature of which had not been definitely determined. About a year and a half before I saw him he began to have very severe headaches, confined mainly to the frontal region. This was increased by study in school, by exposure to the sun, or any excessive heat. The first convulsive attack occurred one year before I saw him. He became much heated after riding a bicycle, became dizzy, and had a short convulsive attack, falling to the ground from his wheel. This was followed by a dull pain and a very uncomfortable sensation, confined to the frontal and nasal region. This pain was much aggravated by stooping. After this first attack they were repeated at frequent intervals, but were usually excited by active exercise, exposure, or any condition that would naturally excite nasal turgescence. The parents became alarmed about the condition of the lad, but no direct connection had been thought by them to exist between the nasal condition and the convulsive attacks, nor by the family physician, who referred the boy to me for treatment of the nasal obstruction. On examination the left middle turbinated bone was found to be very markedly hypertrophied, projecting in the form of a sharp bony ridge against the septum. On the right side the turbinated body was very much hypertrophied, being pressed firmly against the septum. The whole interior of the nose was very vascular, much congested, and very sensitive to slight irritants, although the patient had not suffered from hay fever. The treatment required was clearly indicated; the removal of this intranasal pressure in both the nasal passages—the hypertrophied tissue in one and the hypertrophied middle turbinate bone in the other. After the removal of this pressure not only did the headaches cease, but there were no further indications of any epileptic seizures, and the lad has remained entirely free from them since, now nearly two years having elapsed. He has regained the brightness that he partially lost, and at the present time enjoys a condition of perfect health.

The richness of the nasal region in sensitive nerves makes it possible for us to understand how it is that the nose is one of the organs that most frequently causes neuroses of reflex origin. By no means, however, let us on this account attribute all neuroses to intra-nasal disease, for it is a fact which should never be overlooked that identical nasal lesions can produce with different persons different neuroses.

In one instance we may have epilepsy, in another vertigo, in another chorea, in another supra-orbital neuralgia, megrim, or persistent headache, and in another asthma, while in other cases there may be no reflex at all. As I have elsewhere stated,<sup>1</sup> the explanation seems to be that the nervous force is like an electric current and travels in the line of least resistance. In one case the line of least resistance may be in one direction and in another case in another direction, and thus the manifestations vary according to the anatomical or physiological conformation or variation in different subjects.

As to the influence of the condition of the nervous system in cases of epilepsy, it can not be denied that the ganglionic centers of persons having a susceptible nervous organization are more readily affected by local or reflected irritation than those having a less susceptible organization; but it is by no means true that such natural susceptibility is necessary in order that the neurosis may be excited by the peripheral irritant. A long-continued nasal disease may, and in the majority of cases does, lower the tone of the nervous system and the inhibitory power is thereby lessened. Thus with the continuance of the affection a neurosis is developed that is as much secondary to the primary disease in the nose as the nervous disturbance resulting from an abscess in the ear is secondary to a diseased tooth that may have been the direct cause of the abscess by the irritation of the otic ganglion.

In one of the cases reported by Crossfield, referred to above, the patient's habits were faultless, but he was very much emaciated, with a sallow complexion and a hacking cough, associated with night sweats. His appetite was varying, but generally poor. In the second case the young man was well nourished and full-blooded, rather large for his age, 17. In the second case reported by Schneider, the young woman, aged 24, was strong and well built, and engaged in active outdoor life, being a haymaker. In the fifth case the man was strongly built, but suffered from a number of nervous troubles. Fincke says that the man treated by him was strong and active. The girl cured by Abramson from nightly epileptic attacks, resulting from hypertrophic rhinitis and enlargement of the turbinated bodies, was the daughter of a hysterical mother. The two cases that have come under my observation were by no means of a neurotic habit. As might be inferred then, a severe attack of epilepsy often results from a disproportionately small irritant, owing to the condition of the central nervous system having been previously lowered. With reference to the supposition that natural susceptibility is necessary for a peripheral irritant to produce a marked neurosis, it may be interesting to note that in about one-half the cases of epilepsy cited above as being the result of intra-nasal disease the reporters have mentioned the fact that their patients were naturally well nourished, strong, and active. The portions of the nose of which a diseased condition seems most liable to occasion epileptic attacks are the septum and the middle and lower turbinated bodies. The etiological factors most frequently met with are turbinated hypertrophy, exostosis, and polyps. In the case reported by Fincke, nasal polyps were found in the right fossa. Of the cases reported by Schneider, in two there were polypoid growths, with exostosis of the septum; in two other cases the lower turbinated bodies were hypertrophied, and in the remaining two cases the affection is described merely by the indefinite term "swellings on both sides."

Chronic hypertrophic rhinitis, with enlargement of the left two lower and right middle turbinated bodies, occasioned the epilepsy in the case recorded by Abramson. In the first case reported by Crossfield there was found on the right side marked hypertrophy of the inferior turbinated body, causing almost complete

---

<sup>1</sup> New York Medical Journal, Vol. XLVI, p. 257.

stenosis. On the left side there was marked deviation and exostosis of the septum, while the inferior turbinated body was hypertrophied. In case No. 2 there was absolute nasal stenosis, both the right and left inferior turbinated bodies being hypertrophied. In both of the cases that I have reported the convulsive disturbance was due to the pressure from turbinated exostosis and enlarged turbinated bodies against the septum.

From a careful study of all the cases of reflex disturbance from nasal disease coming under my observation, I have come to regard the septum as the center from which these disturbances most often radiate, and not the sensitive areas in the turbinated bodies, as has hitherto been regarded.

Starr<sup>1</sup> has recently stated that in all cases where local irritation is sufficient to cause epilepsy the patient will have his attention sufficiently directed to this localized disorder to cause the local disturbance to be discovered. In this respect I do not agree with him. Many cases of neurotic disturbance have come under my observation where it was only by the merest chance that the local cause was discovered. Hence we can not emphasize too highly the importance of examining the nose in all cases where the cause of epileptic attacks is at all obscure. That epilepsy has other causes than nasal irritation goes without saying, but that nasal disease is a factor of prime importance in its production has also been fully proven.

### SOME FORMS OF NASAL REFLEXES, WITH REPORTS OF CASES.

By Dr. S. K. MERRICK,

*Professor of Diseases of the Nose, Throat, and Chest, Baltimore Medical College.*

While a few are still skeptical as to the connection between the treatment of intranasal diseases and the cure of certain so-called "reflexes," located in some more or less remote portion of the body, I take it that the great body of medical men, especially among throat specialists, believe the connection to be close. To mention the names of all who have contributed to our fund of knowledge would lead us far beyond the limits of this paper, but it may not be amiss to refer to a few whose labors have thrown special light upon this interesting subject.

Voltolini<sup>2</sup> seems to have been the first writer to bring the question of the nasal reflex to the attention of the profession when he reported a case of spasmodic asthma, due to a nasal polypus, cured by removal of the growth. This observation has since been verified by others.

Seiler,<sup>3</sup> Hack,<sup>4</sup> and John N. Mackenzie<sup>5</sup> subsequently published cases of reflex cough, due to morbid conditions within the nasal cavities. Hack<sup>6</sup> in his monograph reports a large number of reflexes, among them are gastralgia, dyspepsia, cardiac palpitation, tumefaction and redness of the skin of the nose, salivation, neuralgia of the first two branches of the trigeminus, cephalalgia, migraine, ciliary neuralgia, scotoma, photophobia, vertigo, exophthalmic goitre, and others. Elsberg,<sup>7</sup> Salinger,<sup>8</sup> and Bosworth<sup>9</sup> have reported cases of chorea, due to hypertrophic rhinitis. Cases of epilepsy, due to intra-nasal disease, have been reported

by Salinger,<sup>1</sup> Fincke,<sup>2</sup> and Bosworth,<sup>3</sup> while T. A. McBride<sup>4</sup> reports a case of psychical epilepsy. Ziem<sup>5</sup> reports a case of nocturnal enuresis, while North<sup>6</sup> thinks most cases of neurasthemia will be found to have intra-nasal disease. Two cases of salivation of reflex origin are reported by Bosworth<sup>7</sup> and one by E. Frankel, and cited by Rualt<sup>8</sup> and Bosworth, were cured by treatment of intra-nasal conditions, upon which they were dependent. The question of ocular disturbances of nasal origin was forcibly brought to the attention of the profession by Dr. Gruenning,<sup>9</sup> of New York, in a paper read before the Academy of Medicine, in January, 1886. Beverly Robinson,<sup>10</sup> Cheatham,<sup>11</sup> and Bettman<sup>12</sup> report cases of many forms of eye troubles dependent upon intra-nasal conditions. Many names might be added of those who have reported nasal reflexes affecting divers organs, but the foregoing, in view of their eminence and respectability, are quite sufficient to emphasize the fact that nasal reflexes are not uncommon, nor confined to a very limited portion of the economy.

The moral effect has been invoked to explain the action of treatment in effecting cures. I, however, agree with Bosworth that, while "it may have some force," it is purely secondary and adventitious in the great majority of cases, but in a small per cent of them I am constrained to believe it is the chief if not the only factor in achieving the result. Bosworth believes that the successful results are due primarily and mainly to the removal of local intra-nasal disease. In this view I can not fully concur. While this is so in most cases, there remains a small number which are relieved before the morbid condition in the nose is cured, and must be explained on the theory of counter-irritation, which was sufficient to excite healthy action in the nerve centers, presiding over the site of morbid action, before it effected a cure at the site of application.

There are three prominent or chief views held as to just how these reflexes are cured, viz: (1) By moral influence; (2) by counter-irritation, and (3) by removal or cure of the morbid causative condition within the nose. That no one of these theories will adequately explain the *modus operandi* of the curative agent in all cases, I firmly believe; and that all three of them may be necessary to do so, the following cases will, I think, prove:

*Case 1.*—G. S.; male; aged 28; native of Baltimore, Md.; merchant; parents living and well; one brother died of pulmonary tuberculosis, and a sister is suffering with a chronic cough. Patient consulted me November 5, 1892, complaining of intense headache and vertigo, which had persisted, in spite of all remedies, for the past six months, until life had become a burden and he feared sometimes he would "lose his mind" if he did not get relief. As his nose had become more or less obstructed and a sense of pressure over bridge of same was nearly always present, he had concluded that nasal catarrh might have something to do with his distressing headaches and vertigo, and had accordingly come to consult me. An examination revealed in both nasal fossæ, highly inflamed and sensitive turbinates, which were the seat of both false and true hypertrophy. At the second visit, November 7, the inferior turbinate on one side was cauterized, and on the 9th he told me his headache and vertigo were much improved. On the 14th the cautery was again used on the other inferior turbinate, and at his next visit, on the 18th, he told me he was entirely relieved and delighted beyond measure with my treat-

ment. Beyond a slight shrinking of the inferior turbinates I could see little improvement in the intranasal conditions. The marked relief which my patient had experienced seemed out of all proportion to the slight changes effected within the nose. This, together with the fact that a severe rhinitis was still going on, forced me to the conclusion that the nerve centers, responsible for the head symptoms, had been stimulated into healthy activity by the first cauterization, and that the marked improvement which took place within two days could not be due to improvement in the intranasal morbid condition, which was not sufficient to be noticed on the closest inspection at that date. This patient did not return for further treatment after his head troubles, vertigo and headache, were relieved, although his rhinitis was still uncured.

*Case 2.*—A. E. M., male, aged 30, native of Pennsylvania, station agent Pennsylvania Railroad (family history not known), consulted me June 15, 1888. The right nasal fossa was nearly normally patulous, there being slight hypertrophy of inferior turbinate and chronic rhinitis. The left fossa, however, was nearly completely obstructed by a deflected septum and an exostosis which rose up from the inner side of the floor of the nose, half inch from its anterior opening, the two deformities leaving a small triangular opening for respiration. Both fossæ were in a high state of inflammation, and after about two weeks of soothing treatment I operated on the deflection and a week later upon the exostosis. The catarrhal process began to improve rapidly after free respiration and drainage were established. A few days before I was ready to discharge him, he told me one morning with evident delight that the cocaine which I had been using in his nose had restored his eyesight. This was the first intimation I had had that he had defective vision, although I had observed that he wore glasses. He had discarded them the night before, finding he could see better without them. I found upon inquiry his was a case of asthenopia of several years' standing. I of course explained to him that the real cause of the restoration of normal and painless vision was the removal of nasal obstruction and cure of his catarrh, and that the cocaine played no part in it, except as a local anæsthetic during the operation.

*Case 3.*—Miss L. C. B., single, aged 27, born in Montgomery County, Md., weight 145 pounds, above the medium height. Parents living and healthy; six sisters and three brothers, all strong and healthy. She was referred to me by Dr. William P. Chunn, of Baltimore, Md., who thought she had some nose and throat trouble which needed attention. March 1, 1893, I made an examination of patient's nose and found a badly deflected septum of traumatic origin, dating from a fall on the ice, in girlhood, while skating. The knuckle of deflected cartilage was transverse and firmly adherent to the inferior turbinate of the left side, involving the sutural junction between the bony and cartilaginous septum. The middle turbinate was much hypertrophied and pressing down on the knuckle of deflected cartilage, but not adherent to it. The left nasal fossa was, by these deformities, almost completely closed. The inferior meatus of the right fossa was completely filled with an hypertrophied inferior turbinate, which on close examination was found tightly bound down to the floor of nose by adhesions, the result of an operation done by a physician in a neighboring Virginia town, just before she had the grip. Both nasal fossæ were operated on—one with scissors and cautery and the other by means of the saw and cautery, and free respiration and drainage were established. Owing to hæmorrhage from the sawing I found it necessary to plug and replug daily for three days the fossa with cotton wool, and an interesting and instructive feature of the case hangs upon this circumstance, which will be referred to presently.

Twenty-four hours after the cotton tampon was dispensed with my patient returned to my office, telling me I had cured her of a most serious and distressing eye trouble of long standing. I then elicited the following history of her case, as nearly as possible in her own words. Eight years since, she began to have headache and the first disturbance of vision. It became impossible to place a book at the proper distance for reading. When she thought it was right it would immediately get wrong. This difficulty increased, and seeing double and often triple, with blurring, jumbling, and half blotting out of words, constantly harassed her efforts at reading. By the end of six months she could not see well enough to paste pictures in a blank book for a child, and had to desist on account of imperfect and painful vision. She then consulted a prominent oculist of Washington, D. C., who gave her three pairs of glasses, which she wore as directed. These made her condition more tolerable and improved the painful vision, until two years since when she had the grip, followed by measles, when it became necessary to again consult an oculist, who was also a distinguished specialist of Washington, D. C. After some treatment of the eyes, the right eye was operated on for slight external strabismus. Vision after this was easier, somewhat, but reading and

writing were impossible, and vision at all times remained painful, and dread of light was always present. She was to return after a month or two and have the other eye operated on for a similar condition, but fell into my hands before the time arrived for her next visit. I was entirely ignorant of the foregoing history of her eye trouble until she related it to me, four days after I had operated upon her nose.

As long as the cotton tampon remained in the nasal fossa after the operation no improvement in her vision took place, but six hours after it was removed she suddenly discovered that she could read by gaslight with perfect comfort, and at once seated herself and wrote a letter to her mother, without glasses, telling her of the "glad news." She had been unable to write for several years. It was the following morning she informed me of the result of the operation upon her eyes. She remained under my care for about two weeks, during which time her vision remained easy and good, and I have a letter dated July 29, 1893 (about four months after the operation), in which she tells me she has just paid a visit to Dr. M., of Washington, D. C., and he frankly admits that my treatment of nose has rendered it unnecessary to operate for strabismus on the other eye, and that there is not the least doubt about the benefit which resulted from the operation.

*Case 4.*—J. S., male, aged 45, married, engineer, enjoyed good health until six weeks previous, when he was compelled to stop work on account of great pain in right thigh and hip. Patient consulted me October 12, 1887; at that time he was walking with a cane and limping badly. It transpired that he had been relating his case to a neighboring barber, who was under the impression that nearly all ailments were caused by catarrh, and insisted that my patient should consult a throat specialist at once. I learned the names of two reputable physicians who had been treating patient since his trouble began, but no relief was realized. The man had become convinced that all his trouble in leg was dependent upon "nasal catarrh," and that when the latter was cured he would get well of the former. I frankly told him that there was no connection between the two affections. I found on examination a mild chronic rhinitis, most marked in left inferior turbinate, which I told patient I would operate on, and did with the galvanic cautery. Two days later patient returned, walking without a cane and with a very slight limp, saying he began to get better on leaving my office at his previous visit. At his next visit he declared himself well, and has remained so to this date. No one can convince him that he was not cured by the electro-cautery. I saw little or no change in the intranasal condition, and it is possible that it had no connection with the sciatica, with which the man was suffering on his first visit, but that the case was one similar to that of Bouchard, referred to by Bosworth in his book, volume 1, page 197, where a case of sciatica was cured by cauterizing the lobe of the ear. The description which he gave to the barber of the operation, and of his feelings during the progress of the same, lead me to the conclusion that the "moral influence" was the chief if not the only factor in effecting the cure.

This case, however, is reported to invite the opinions of others and some rational explanation of the connection which exists in such cases between the cauterization and the morbid action so remotely situated, and not with the view of expressing any very definite opinion of my own. The following deductions, I think, may be fairly drawn from the foregoing cases, viz: (1) That distressing headaches and vertigoes, apparently dependent on chronic rhinitis, may yield to intra-nasal cauterization before the catarrhal process is appreciably improved. (2) That the most serious ocular disturbances may be due to intra-nasal disease, and that pressure irritation may be the chief factor in such conditions, and that removal of same may yield the most brilliant results. (3) That pathological processes or symptoms, remotely situated, are, occasionally, unexpectedly relieved by cauterizing the turbinates.

In the preparation of this paper I have freely consulted Bosworth (*Diseases of Nose and Throat*).

## DISCUSSION.

Dr. PRICE-BROWN, Toronto. I can not say that in my experience I have seen any cases of epilepsy that I could trace to neurosis of the nasal cavities, although I have certainly seen some exceptionally nervous patients with neurotic symptoms of that nature that might possibly develop into an epileptic form. A case of that character came under my observation recently. It was that of a lady, about 50 years of age, who had been troubled with sore eyes for several years. There was a good deal of discharge and a constant running of tears over the face, so that she had, on a number of occasions, gone to an ophthalmologist, who had passed an instrument down the nasal duct in order to free the passage to the nasal cavity. Although this was done repeatedly, she still had the same trouble of tears running over her cheeks, and finally she came to me. I examined the nasal passages, the left one in particular, and found there was a large hypertrophy of the middle turbinate of the left side pressing against the septum. This hypertrophy, from which a discharge of pus took place, was very painful. I operated upon it with the galvano-cautery, and removing the hypertrophied tissue I discovered that the middle turbinated bone itself was pressing into the septum. I sawed a portion of it off, with the result that there has been a complete cessation of the eye symptoms. There is no more running of tears over the face, there is no tendency to conjunctivitis, and the associated ophthalmological neuralgia has passed away. Of course, the discharge of pus from the antrum still continues. It may be possible that the pus, not escaping sufficiently, might give rise to the other symptoms; but as the occlusion was only on one side, while both were affected, it seems to me to be largely a reflex condition.

Another case was that of a young lady who had hay fever for fourteen years; she is 25 years old now and she has had the disease since she was 12. Hay fever in her case had the peculiarity of commencing in June and ending about the 1st of August. On examination I found the columnar cartilage completely filling in the right nasal cavity, pressing against the septum; of course she could not breathe on that side. I cut through the mucous membrane and with saw and scissors cut out one-half of the columnar septum and by means of a tampon kept the nares open. The result was that all the symptoms of hay fever which she had when she came to me passed away and she has had none since. I think the symptoms of hay fever in her case arose principally from the pressure of the columnar cartilage against the ala of the nose.

Dr. S. SOLIS-COHEN, Philadelphia, Pa. I have been much pleased with the moderate tone of the paper read and the judicial nature of the conclusions arrived at. I suppose some members of the section at least are familiar with the position I have taken, opposing the extravagant assertions made by men of insufficient experience in describing a large variety of diseases as solely due to morbid conditions of the nasal chambers, it having been my fortune to meet with many cases of such conditions in conjunction with diseases of the nasal chambers, in which I purposely refrained from local treatment in order to test the dependence of so-called reflex symptoms upon the nose or upon constitutional conditions. The cases stated by Dr. Roe are, however, beyond criticism. The epilepsy in these cases, so far as I am able to judge, must have been due to the conditions of the nose which he relieved. I have no criticisms to make of Dr. Merrick's cases. Scattered throughout the literature here and there are such undoubted cases, and there must be others unpublished. I am inclined to believe, however, that many of the cases reported of reflex disturbances due to nasal conditions are not dependable. Some of the cases appear to have been insufficiently studied, in others the conclusions are not justified by the reported facts, and in some instances with

which I am personally acquainted the reporters have not had sufficient acquaintance with general medicine to be able to exclude the general causes. In this connection I would like to differ somewhat with Dr. Roe as to the necessity of the neurotic substratum for these manifestations. I believe such neurotic disposition to be essential. It may not, however, give rise to marked phenomena in the absence of peripheral irritation in the nose or elsewhere. I have recently investigated a number of cases presenting certain neurotic phenomena in the domain of the vaso-motor system. In some instances there is apparently a very slight departure from normality. It would not attract attention unless sought for, yet when the cases come to be studied and investigated from all standpoints the evidences of instability in the circulatory mechanism will be found. I should not be at all surprised if in many cases of reflex disturbances from nasal irritation the patients would, upon investigation, be shown, as some of my hay-fever patients have, to have this neurotic instability of circulation, which would account, when mechanical causes are insufficient, for the vertigo and for the disturbance of vision. In some of my cases ocular disturbances have been quite prominent, and even epileptic attacks are among the phenomena associated with this condition. I find the same thing existing in several members of a family, and in some instances there has been marked heredity. I would ask Dr. Roe and the members of the section, in future cases of apparent nasal reflex neurosis, to investigate especially two features of the case. First, whether cardiac action can be disturbed by slight causes, causes that in a thoroughly normal individual would not be adequate to effect such disturbances; and, second, whether the phenomenon called dermographism can be produced. The test is made by writing with a probe upon the skin of the patient at any point, say on the inner surface of the forearm, the skin having been made tense by clinching the fingers. Light pressure is used. In a very few moments the device traced will stand out in bright red characters, and in some patients in a few minutes large welts will appear resembling the welts of urticaria; in others deeper pressure is required to produce this factitious urticaria, and in some who are still less susceptible the additional application of cold. I do not know that these conditions are present in nasal reflex, because, unfortunately, in the 50 cases I have studied there was none in which I was able to discover any condition in the nasal chambers which I would consider adequate as a source of peripheral irritation. The cases reported by Dr. Merrick of ocular disease are certainly interesting; and conversely to them are the cases stated by Gould, in which correction of ocular defects cured nasal catarrh and hay fever. The question of moral effect, raised by Dr. Merrick, is most surely one which can not be excluded in considering some of these cases. In Dr. Roe's cases of epilepsy there was hardly room to suspect merely moral effect. In the cases of sciatica reported by Dr. Merrick, and in some others, moral effect must, however, play a large part. I remember having reported to the American Laryngological Association some years ago a case of obstinate sneezing in a patient who insisted upon having her nose cauterized in order to cure it. I did not cauterize it, but she did not get well until I said I would apply an electric current. I applied a constant galvanic current, and thinking it was the cauterization which she had insisted upon having applied, the patient promptly recovered. That surely points to more than a suspicion of moral effect. In conclusion, I would allude to a class of cases, one of which has but recently been under my care, in which with marked intra-nasal exostosis there coexists headache associated with a sense of pressure at the root of the nose, and with sensitiveness to pressure over the intra-orbital and supra-orbital foramina. In about half a dozen such instances I have seen the headache, which occurred periodically, disappear upon treatment with quinine hydrobromate, administered four to six hours before the attack in order to have its maximum effect at the time of the expected paroxysm. This drug is

usually administered in conjunction with ergot in order to prevent any bad effect of the quinine upon the ear. The combination of quinine hydrobromate and ergot having relieved these headaches while I have left the nasal deformity untouched, and on the other hand, as in a case specially reported, skillful treatment of nasal conditions at other hands than mine having failed to give relief to headaches that afterwards yielded to medication, I am constrained to minimize the nasal factor in many cases. I believe there must be quite a large number of such cases. Others probably see many more of them than I do, because, being in general practice, the number of nasal cases I see is not so great as that seen by other members of this section.

Dr. A. W. DE ROALDES, New Orleans. I fully agree with Dr. Cohen and Dr. Merrick when they call attention to the fact that persons affected with reflex troubles from intranasal disease are not always to be looked upon as belonging to the constitutionally neuropathic class of patients. In order to emphasize this point allow me to refer to a case which came under my observation a few weeks ago. The subject was a country girl of about sixteen years of age, who was brought to my office for some aural trouble on one side. She was a fine specimen of country life, in exceedingly good health, of strong nerves; could ride a horse, fire a gun, and feared nothing. Menstruation was normal. The drum on the affected side was opaque and somewhat retracted, the hearing having diminished considerably on that side in the last eighteen months. Mouth breathing was observed, due to intranasal obstruction, the result of an osteo-enchondromatous deviation of the septum on side of the affected ear. I suggested an operation to relieve at once the nasal trouble, which would allow me afterwards to treat the ear. Cocaine was applied, and the obstruction mostly sawed off, when all at once, as the instrument reached the upper and posterior part of the bony ridge, the girl complained of a severe pain in the head, especially in the supraorbital region, with a marked disturbance of respiration. The pulse rose to about 118, she was pale and fainting; whisky had to be administered and the operation hurriedly finished. At the time I attributed these symptoms to the effect of cocaine, for I had used it in a rather strong solution. All at once the patient began to cough and she coughed for two hours, one of those harrowing, incessant, short, expiratory coughs. Everything was tried to relieve this painful symptom. Primary anaesthesia with chloroform, pushed even to the point where the eyeballs were made insensible to the touch, would but partially relieve the cough. I had finally to resort to a hypodermic injection of one-third of a grain of morphine, which allowed her removal to her home. That condition kept up for three days, when to procure rest the family physician had to resort several times to the use of morphine hypodermically. After three days the cough had mostly disappeared and the condition much improved, when she reported to the office in my absence. My attendant, Dr. Scheppegrell, had scarcely inspected the intra-nasal wound and resorted to a very gentle mopping when the girl began to again complain of pain in one side of the head, with irritation behind the ear and in the neck, and the same violent cough returned. This time electricity was resorted to, with temporary relief. The cough nevertheless returned after she had reached home, lasted a whole week, giving the young woman only three or four hours of sleep, depressing her, and interfering seriously with nutrition. A third attempt to clean out the nasal passage, on the eleventh day, brought about the same state of affairs, lasting about twenty-four hours. After such an experience the parts were left undisturbed and the intra-nasal wound left to heal up naturally; henceforth the girl's condition improved, and she has never had a recurrence of the cough, which, as a result of the operation, had for fourteen days rendered her life miserable. The second and third attempts at treatment were made for the sake of clearing a possible doubt without the use of cocaine. This is as marked an example as I have seen of a nervous trouble, set up evidently

as a reflex by the traumatic effect of the operation, in a strong and healthy young woman, devoid of any neuropathic taint. In such cases the reflex troubles are, I think, better explained by some direct nervous communication, especially when developed in the area of innervation of the exciting intra-nasal disease, or in its immediate vicinity, where nervous anastomoses or continuity of tissue can be invoked. Suggestion will be of no avail in the relief of such cases. On the other hand, I am inclined to accept its good effects in cases of neurasthenic patients, in whom the reflex troubles are developed at a distance.

Dr. F. C. COBB, Boston. I would like to ask how long relief lasted in these cases, the epileptic ones especially? I have found in cases of vasomotor rhinitis that when the obstruction was removed the asthmatic symptoms were very much relieved for a time, but in a year they almost always returned, yet the nose remained almost clear. It seems to me that time is a great factor in deciding how much is suggestion and how much cure.

Dr. S. K. MERRICK, Baltimore. I should like to ask Dr. Cohen in the cases he referred to with vertigo and headache where there was pressure over the bridge of the nose similar to one of the cases I reported, what doses of hydrobromate of quinine he gave, and whether or not the cure in these cases was permanent.

Dr. COHEN. The dose varied from 10 to 30 grains, the 30 grains being given in two doses. The cure in two cases was permanent; in one case the gentleman came under treatment but a short time ago and I am unable to say what the result will be; the other case I have been unable to hear from since.

Dr. MERRICK. In the case I reported there was a great deal of sensitiveness and both false and true hypertrophy were present. It seems to me that anything that will control the circulation or get possession of the nervous system is desirable. I think quinine exercises a great deal of influence in hay fever, and that condition is simulated in many of these cases such as I related. Ergot also controls the circulation, but it simply emphasizes the fact that if the circulation is controlled and the pressure relieved that it will not militate against the idea or assumption that the case was originally one of reflex origin, reflected from that point of irritation; simply controlling the circulation by hydrobromate of quinine does not show that it was not originally caused by pressure irritation within the nose. One point I would like to answer that refers more especially to Dr. Roe's paper; that is in regard to time. I stated that in one of my cases the man had remained well since 1887, and he is still well. One of the eye cases I followed for six or seven months, the case that believed himself cured by the use of cocaine. In the last case of ocular disturbance it has been about four months, and the patient is now using her eyes as well as ever.

Dr. JOHN O. ROE, Rochester, N. Y. In regard to the points raised by Dr. Cohen as to the uncertainty of this condition being due to local irritation as a primary factor, or to a constitutional condition, I think it would be difficult to establish that fact, as we have no means of estimating exactly how much general disturbance the local irritation has caused. We can not say that the general disturbance has not been the result of the local irritation or that the general constitutional impairment of the system has not caused the present susceptibility to this local irritation. We know that if we have so simple a disturbance as a toothache for a short time we become very much depressed, our inhibitory powers are lessened, and the circulatory system much disturbed. So any local irritation in any portion of the body may manifest itself in a general neurotic condition or a disturbed condition of the circulatory system. In a great many of these cases we find a primary weakened condition, causing a proclivity for these disturbances which a local irritation readily develops, but we can not say positively that in a great many cases the local irritation has had a great deal to do with bringing about a condition that may be the exciting cause of epilepsy. In regard to the general

treatment of these cases, in which we have a central disturbance induced by a local cause, it may be said that the administration of drugs, such as those that will quiet the nervous excitability or will so deaden the afferent nerves that the local irritation ceases to be communicated to the brain centers, will have the same effect as if we remove the exciting cause. Consequently, the medication has but the effect of stopping the paroxysm for a certain length of time, or during the continuance of the effect of the drug. It is, however, of the utmost importance to resort to restorative and supporting measures, for in all of these cases, whether due to a primary central disturbance or a local cause, there is always a lowering of the tone of the general system, in very much the same way as a short-circuited electric wire will prove a marked drain upon the main electric current. In regard to the length of time these patients were under observation, in case 1, four years have elapsed since the patient was under treatment, and she remains at the present time perfectly well. In case 2, two years have elapsed since treatment was discontinued, and the patient is in perfect health.

---

IMPORTANCIA DEL ESTUDIO MICROSCÓPICO DE LAS MUCOSIDAS LARINGEAS, PARA DESCUBRIR OPORTUNAMENTE LA INFECCIÓN TUBERCULOSA LARINGEA É INSTITUIR UN TRATAMIENTO CONVENIENTE.

Por el Dr. ANGEL GAVIÑO,

*Profesor adjunto de Higiene, Profesor de Bacteriología de la Escuela de Medicina de México, Médico del Consultorio Central de Beneficencia y Secretario de la Academia de Medicina de México.*

SEÑORES: Todos vosotros que habeis observado la laringe en numerosos casos, podreis haber comprobado el hecho de que en general la mucosa laringea no presenta caracteres especiales en el principio de la tuberculosis de este órgano. Ciertamente es que la hinchazón y la palidez de los cartílagos aritenoides y de la epiglotis en la tisis laringea son un buen signo de presunción, sobre todo cuando existen en el enfermo otros del lado de las mucosas ó de los pulmones; que los antecedentes de la familia, que la proximidad de personas tuberculosas, y otros elementos, pueden hacer suponer que haya una tuberculosis laringea si el funcionamiento del órgano se modifica y los síntomas de inflamación crónica se acentúan. También puede ser casi indudable el diagnóstico cuando se han demostrado degeneraciones necróticas tuberculosas, ulceraciones clásicas, en las encías ó en la faringe. Estas degeneraciones, estas ulceraciones de pequeñas dimensiones y muy numerosas, con tendencia á la reunión y á extenderse en superficie más bien que en profundidad, son ya un signo demasiado elocuente para que el clínico ponga en duda la infección tuberculosa de la laringe; sin embargo, algunos prácticos muy notables han incurrido en error cuando se han fijado solo en el aspecto de las pequeñas ulceraciones y en otros de los signos reputados como casi inequívocos, ejemplo de ello es Heinze, quien habiendo observado en 1876 á 50 enfermos en el Hospital Jacob, los cuales fueron elegidos entre los que presentaban todos los caracteres de la tuberculosis pulmonar, declaró ser las ulceraciones laringeas tuberculosas, convenciéndose después de que de estas ulceraciones solo el 83 por ciento lo eran y el 17 por ciento no lo eran. Esto significa que aún en el período de ulceración ó cuando este se inicia, es algo inseguro el diagnóstico y que en estos casos como en aquellos de presunción, y aún en los que se reputan como simples laringitis catarrales crónicas, es necesario otro elemento que como el microscopio ayude á aclarar cuanto ántes la naturaleza de la afección.

Pues bien, en varios enfermos que se me han presentado pidiendo tratamiento de su laringitis crónica, y en los que solo existía enrojecimiento é hinchazón de

la mucosa con ligero enronquecimiento de la voz, he hecho el exámen microscópico de las mucosidades adherentes tomadas con un pincel fino en los repliegues de la mucosa, ya en la base de la epiglotis, en su cara laringea ó en los antros de Morgagni, y he encontrado en algunos el bacilo de la tuberculosis, siendo así que por el exámen laringoscópico no estaba autorizado á dar un diagnóstico seguro y no podía inclinarme á la existencia de una laringitis tuberculosa.

El conocimiento de la naturaleza de una afección cuando aún no se encuentran comprometidos órganos importantes ó que la infección no se ha generalizado, es de todo punto necesario si se quiere obtener un resultado con los elementos médico-quirúrgicos de que actualmente disponemos. Esta idea muy general ha sido reforzada en su importancia con el importante estudio previo de las mucosidades faringeadas de los supuestos difteríticos, pues ha venido á enseñarnos que cuando el clínico aún no puede pronunciarse por el diagnóstico de la difteria, ya el microscopio y las culturas en suero, denuncian la presencia del bacilus de Löffler, y proporcionan al práctico un conocimiento de colosal importancia que le permite combatir la afección en su principio, y por consiguiente multiplicar las probabilidades de éxito.

Si en la difteria se alcanzan hoy brillantes resultados, como pasa en el Hôpital des Enfants Malades de Paris en el servicio del Dr. Simon, ¿porque no aplicar el mismo medio en todos los casos en que una laringitis comienza á hacerse duradera y refractaria á los medios terapéuticos comunes en las afecciones catarrales?

Siempre recuerdo, para enseñanza, de lo que reputo como necesario del exámen microscópico en todos los casos ligeramente sospechosos, á dos enfermos, uno hombre, el otro mujer, quienes durante algún tiempo fueron tratados como afectados de un catarro crónico simple laringeo, por presentar un ligero edema glótico con enrojecimiento de la mucosa y una ronquera y afonia incompleta intermitentes y que al cabo de nueve años han caído en mis manos, y he podido demostrar en el hombre una necrosis tuberculosa de los cartílagos aritenoides y de la epiglotis y la destrucción del ligamento ventricular izquierdo y de la cuerda vocal izquierda, y en la mujer un inflamamiento considerable al nivel de los aritenoides, más el del lado derecho, y una ulceración irregular y granulosa en el repliegue inter-aritenoideo derecho. En ambos casos la demostración del bacilus tuberculoso no dejó lugar á duda respecto al diagnóstico. No es indudable que si en estos casos ó en otros semejantes, se demuestra con tiempo la naturaleza específica de las lesiones, se podrán evitar, retardar, ó disminuir los terribles destrozos que pueden sobrevenir posteriormente,

En los enfermos en los que bien temprano he podido demostrar la presencia del bacilus de Koch he instituido el siguiente tratamiento que me ha dado muy buenos resultados:

(1) Inyecciones intra-laringeas, tres veces por semana de la siguiente solución:

|                                  | Gramos. |
|----------------------------------|---------|
| Aceite de almendras dulces ..... | 100     |
| Creosota de haya .....           | 3       |
| Salol .....                      | 3       |
| Salicilato de bismuto .....      | 2       |

S. Inyección intra-laringea.

(2) Aplicaciones con el pincel en los repliegues de la mucosa laringea de una solución de cloruro de zinc y sublimado:

|                       | Gramos. |
|-----------------------|---------|
| Cloruro de zinc ..... | 5.00    |
| Sublimado .....       | 0.05    |
| Agua destilada .....  | 90.00   |
| Glicerina .....       | 10.00   |

S. Toques para la laringe.

(3) Tres píldoras diarias de la siguiente fórmula :

|                        | Gramos. |
|------------------------|---------|
| Creosota de haya ----- | 1.00    |
| Guayacol -----         | 1.00    |
| Extracto de opio ----- | 0.15    |
| P. Píldoras No. 50.    |         |

Tanto las inyecciones de un gramo, como los toques laringeos, los enfermos los toleran muy bien, y he podido continuarles el uso cotidiano de las píldoras de creosota durante muchos meses sin el menor inconveniente.

Periódicamente he estudiado las mucosidades laringeas al microscopio y he podido notar la disminución progresiva de los bacilus. En tres enfermos han desaparecido casi completamente se puede decir, pues con trabajo se encuentra uno que otro en la preparación, y los síntomas se han mejorado en dos de ellos al grado de no presentar molestia y de haberse reducido la hinchazón laringea sin que aparezca el aspecto pálido opaco de una mucosa tuberculosa.

Creo por tanto necesario el que en ningún caso, por poco sospechoso que sea, se deje de recurrir á este medio diagnóstico que oportunamente permitirá al especialista instituir un método curativo tal vez eficaz.

#### THE TREATMENT OF CERTAIN CASES OF CHRONIC CATARRH.

By Dr. ANGEL GAVIÑO, City of Mexico,

[Abstract given by Dr. A. W. de Roaldes.]

Dr. Gaviño wishes to call attention to some cases of apparently chronic catarrhal affection of the larynx; those cases which after having been treated prove rebellious to the treatment. He calls attention to the fact that, in his opinion, from his experience, in some of these cases it is advisable to examine the laryngeal secretions microscopically; that is, in those cases where nothing objectively in the larynx or chest would permit one to suspect any tubercular affection. In such cases he has had the laryngeal secretions examined and has even gone so far as to scrape the mucous membrane; but only in cases where there is no infiltration or ulceration that might lead to the suspicion of tuberculosis, and in such cases he has found in the secretions or the scrapings, Koch's bacillus. This has been a sufficient reason to him to carry on that practice systematically and he has been able in that way to diagnose laryngeal tubercular trouble and to institute the proper treatment in time and long before the objective symptoms, either of the chest or the larynx, would have led him to believe that he had to deal with tubercular trouble. Accordingly, he suggests the advisability in those cases of making a microscopic examination of the secretions and even scrapings of the mucous membrane of certain parts—the arytenoid cartilages, false folds, ventricular bands, and epiglottis. The treatment he suggests is laryngeal injections of an oily substance containing creosote, salol, and salicylate of bismuth, local application of bichloride of mercury and chloride of zinc, and creosote given internally. His conclusion is that even in apparently healthy mucous membrane, where nothing attracts the attention but the rebellious condition of the part to treatment, microscopical examination of the secretions and scrapings of the mucous membrane will often reveal the bacillus tuberculosis when we least expect it, and we are in that way able to institute early germicidal treatment, especially creosote.

## DISCUSSION.

Dr. D. BRYSON DELAVAN, New York City. This is certainly a most interesting paper. The plan proposed is a decidedly new departure, different, so far as I am aware, from any we have heard of before. There are without doubt instances in which tubercular disease seems to develop primarily in the larynx, more probably than we are aware of, because of the difficulty of the diagnosis. If this means could be carried out, with reasonable skill on the part of the practitioner, it would seem, as the writer of the paper has indicated, that in a certain number of cases at least an early diagnosis might be reached. I hope that the paper may be translated and we may have the pleasure of reading it in English, as it seems to me to embody a very valuable suggestion.

---

ALUMNOL, ITS EXCELLENT PROPERTIES FOR USE IN THROAT AND NOSE PRACTICE; A NEW ANTISEPTIC AND ASTRINGENT.

By J. MOUNT BLEYER, M. D., of New York City,  
*Visiting Laryngologist to the West Side German Clinic, etc.*

Following upon the discovery of kairin, the first of the series of synthetical substitutes for chinin, and that invaluable one, antipyrin, together with naphthol, resorcin, urethan, methylene blue, benzoïnol, and others of the same group introduced to us by those excellent chemists, Meister, Lucius & Bruning, of Hoechst, Germany, comes another of their preparations for which, after careful trial and investigation, I predict a long career of usefulness. I refer to alumnol, which only recently was isolated and prepared by Drs. Heinz and Liebrecht also, those chemists who first demonstrated the possibility of building up alkaloids in the laboratory, and were the ones who gave to us the new synthetical medicaments now passed beyond the stage of experiment, whose value as combatants of disease can not be underrated. Kairin, for a long time after its discovery, was regarded as one of the many curiosities that are born in the chemical laboratory, only to remain as such; and so, too, was the early fate of its successor, antipyrin, which, as we all know, has since become one of the most valuable therapeutical agents in our pharmacopœia. It is only since the days of Dalton, Gay-Lussac, Dulong and Petit, Mitscherlich, Berzelius, Avogadro, Faraday, Whöler, and others that the chemist sees in the past course and present tendency of organic chemistry the strongest proofs of the influence and value of the doctrine of Dalton and of these other scientists. Within the past few years many of the new synthetical<sup>1</sup> remedies have found their way into our materia medica, and a knowledge of their nature, history, and properties is essential to every progressive medical man whose aim it is to keep abreast of the rapidly developing pharmacology of the age. My object is, before entering upon the discourse regarding alumnol, etc., which is also one of these synthetical compounds, to trace historically part of the development of synthetical chemistry, in order to make it clear to those not so thoroughly versed in this branch of science.

As far back as 1823 Gay-Lussac and Liebig clearly recognized the existence of isomerism.<sup>2</sup> It is in the domain of organic chemistry that isomerism finds its numerous and most striking examples. Isomerism, after its recognition, showed the fact that the same elements may combine together in the same proportions and yet give rise to totally distinct compounds, and also that fact that it must

---

<sup>1</sup> Synthesis—meaning in chemistry the uniting of elements into a compound.

<sup>2</sup> In chemistry this term means: Identity or close similarity of composition and molecular weight with difference of physical or of both physical and chemical properties.

ultimately depend on difference in the mode in which the atoms of the constituent elements are combined. The discovery of the identity in qualitative and quantitative composition of silver fulminate and silver cyanate by these chemists was in reality one of the most momentous discoveries of the century. These were followed quickly by new discoveries in that direction by other chemists. As these many facts were born and made known to the science of chemistry they profoundly influenced chemical thought by demonstrating that the attributes of bodies depend not merely on the nature and number of their components, but also on the mode in which these components are arranged and distributed. Chemists for the first time clearly recognized that their business was not only to determine the quality and quantity of the various atoms in a compound, but also the manner in which those atoms were grouped and held together. This, indeed, is the great problem of modern chemistry, and each successive theory of the last half century may be valued in proportion as it has ministered to this end. The idea of atomic grouping lay at the basis of the doctrine of radicals, by means of which the chemists of sixty years ago sought to make evident that organic compounds are fundamentally similar to organic substances. It lay, too, at the basis of the unitary views, which, with the discovery of the principle of substitution by Dumas, began to gain ground in organic chemistry. The fact of substitution, indeed, is as inexplicable as the law of multiple proportions, except upon the atomic hypothesis. The nucleus theory of Laurent and the different type theories of the French school, and of their successors in England, all tacitly recognized the existence of atoms.

The limits of this paper preclude the possibility of the attempt to show how these various theories have given place to more rational modes of viewing the structure of organic compounds. Unquestionably the two most powerful factors in determining the present character of organic chemistry have been: firstly, the recognition by Frankland, 1852, of the fact that the atom of every element is inherently endowed with a specific combining power, varying within certain limits, whereby it is able to unite with a definite number of atoms of other elements; and secondly, the hypothesis of Hekule and Couper, which graft themselves directly on Frankland's discovery, concerning certain peculiarities in the mode of combination of the element carbon, the organic element par excellence. Although nothing is known as to the real cause of valency, that is to say, of the cause which enables the atoms of carbon to take to itself and hold in stable union four atoms of hydrogen or of chlorine, and no more than four, and which forbids the atom of hydrogen or of chlorine to do the same thing as regards carbon, it will be obvious that the fundamental idea of valency is essentially atomic in conception. From this time the attempts of chemists to unravel the internal structure or constitution, to use the term first introduced by Butlerow, of organic compounds, took a new departure. Great numbers of compounds hitherto unknown and undreamt of were prepared because theory indicated their existence. The mode of genesis and the nature of the transformations of these bodies threw fresh light on the manner of the grouping of the atoms in bodies already known; and the knowledge thus gained enabled chemists to conceive the methods by which such bodies might be synthetically prepared. Indeed, it may be safely asserted that whenever the constitution of an organic substance is clearly made out the synthetic formation of that body comes within the sphere of practical chemistry. It may not be uninteresting in this connection to take a short survey of the progress which has been made in synthetical chemistry during the last fifty or sixty years. Such a survey, however rapid, will take us into every department of the organic world. During the past half century the chemist has succeeded in forming the active principles or characteristic products of many plants; he builds up substances which have hitherto been regarded as made only by the very process of

living of an animal; and he has formed substances which were thought to be produced only by changes in organized matter after death.

That particular day in 1828 when Wöhler first observed the transformation of ammonium cyanate into urea should be accounted a red-letter day in the history of science. This discovery virtually gave the death blow to the notion that the operations which are concerned in the formation of the chemical products of the organic world are fundamentally different from those which take place in the inorganic world. Urea, or the final product of a series of tissue changes, is pre-eminently a typical product of animal life; no more characteristic example of a substance formed by the action of the so-called vital force could possibly be adduced. By demonstrating that urea can be made synthetically by ordinary laboratory processes and from substances inorganic in their origin, Wöhler proved that vital force is only another name for chemical action, and that an animal is nothing but a laboratory in which a multitude of chemical changes, similar to those which occur in our test-tubes and controlled by essentially the same conditions, is continually taking place. Since the date of Wöhler's discovery, urea has been synthetically prepared by many reactions. Thus it was obtained by Natanson and Basarow by the action of ammonia on carbonyl chloride. This and the other reactions have a special interest from the circumstance that all the substances taking part in them can be formed directly or indirectly from their ultimate elements. Associated with urea as a product of the oxidation of the nitrogenous compounds in the organism are uric acid, xanthin, and sorcin. These bodies are met with in greater or less quantity in urine and in certain forms of urinary calculi, and they are invariably present in the blood and muscle juice. In chemical composition they differ from each other simply in the amount of oxygen they contain. Urea was first artificially transformed into uric acid by Horbaczewski. Its synthesis has also been effected by Behrend and Roosen. Closely related in chemical composition to these bodies are theobromine and caffeine, the active principles respectively of cocoa, coffee, and tea. The widespread use of caffeine-containing products is undoubtedly of great physiological import, and its interest is enhanced by the intimate relationship which is now shown to exist between caffeine and the products derived from the oxidation of nitrogenous matters within the organism. Xanthin, indeed, has been recently transformed into theobromine by Emil Fischer.

Of late years much attention has been paid to the study of the putrefaction of albuminous substances of animal origin with the result that a considerable number of basic nitrogenous bodies, some of which are highly poisonous, have been isolated. These compounds were classed by the Italian toxicologist Selmi under the generic name of ptomaines. They are the products of the vitality of the micro-organisms which are concerned in setting up the putrefactive change. Their discovery has greatly modified our views as to the mode of action of pathogenic organisms, and it is now regarded as not improbable that the disturbances are due rather to the presence of these poisonous compounds. It ought to be stated, however, that the attempts hitherto made to isolate the toxic substances which may be formed by the growth of pathogenic organisms have been attended with only partial success. Thus Nencki was unable to detect any toxic substance among the products of anthrax and staphylococcus aureus, a common organism in abscesses which yields only a nonpoisonous base. On the other hand Briegger, to whom we owe the detection of a large number of these so-called cadaveric alkaloids, has found that the typhoid bacillus yields a poisonous substance which he has named typhotoxine; and he has also discovered that the bacillus of tetanus forms a base now called tetanine, which gives rise to symptoms which have a strong resemblance to those occasioned by the inoculation of the bacilli.

All the ptomaines hitherto isolated are comparatively simple in composition and not very complex in chemical constitution. Some of them have been shown to be identical with bodies already known. Thus choline, a nonpoisonous alkaloid found in bile by Strecker, in the brain and in the yolk of egg, and now known to be the product of the putrefaction of meat or fish, has been synthesized by Wurtz; whilst neurine, a derivative of brain substance, originally confounded with choline, but differing from it in composition and in possessing intense poisonous properties, has been artificially produced by Baeyer and Hofmann. Choline and neurine are closely related substances, and can be readily transformed into each other. Another of the so-called corpse alkaloids, cadaverine, has also been synthetically formed by Ladenburg.

In 1870 Schmiedeberg and Koppe isolated the poisonous principle of the fungus *Agaricus Muscarius*, which they named muscarine. Subsequently muscarine was obtained synthetically. It is, however, among the products of plant life that some of the most valuable syntheses of modern times have been effected. Tartaric acid, the characteristic acid of unripe grapes, and citric acid, the acid which gives sourness to limes, lemons, and oranges, have each been artificially prepared.

Many attempts have been made at various times to effect the artificial formation of vegetable-alkaloids, such as quinine, morphine, strychnine, etc., but as yet with only partial success. There is little doubt, however, that such synthesis will be accomplished when the constitution of these complex substances is better understood. Up to the present time only two alkaloids have been synthesized, one completely, viz, conine, and atropine. A considerable number of the odoriferous principles of plants have been obtained artificially, such, for example, as bitter-almond oil and oil of mustard. Salicylic acid, vanillin, and alizarin are now also synthesized. The remarkable industrial results which followed Graebe's and Liebermann's discovery from coal-tar derivatives, which completely destroyed a staple trade of France, Holland, Italy, and Turkey, naturally roused chemists to attempt the artificial formation of a dyestuff not less important, viz, indigo. This has been accomplished, independently, by Baeyer, by Heumann, and by Heymann. No synthesis of recent years has created a keener or more widespread interest than that of the sugars, dextrose and lævulose, which has been recently effected by Emil Fisher. It is interesting not merely as an instance of the artificial production of well-known substances, but also on account of the light it is calculated to throw upon the origin and mode of formation of the sugars in the vegetable kingdom. This has been accomplished through the medium of glycerin. The advance in every section of chemistry during the latter half of it has literally been by leaps and bounds. Although practically a creation of our own time, no branch has been more fruitful in result, in suggestion, or in possibility than that of organic synthesis. The mere gain in the knowledge of fact is immeasurable; it is even more impossible to gauge the profound effect of that knowledge on other departments of human effort and intellectual activity. Past history shows only too well that there is a tide in the affairs of science, as in all other things, that constitute affairs of men. There are periods of ebb and flow, of advance and retrogression. But of this we are certain: in chemistry the flood has only just set in, and it is still very far from high-water mark.

Alumnol is a remedy to which I desire to call the attention of my colleagues, the laryngologists, on account particularly of its antiseptic, astringent, and highly non-poisonous properties, which, by the way, are its marked characteristics, and which alone must give it prominence as one of the most useful agents in our branch of practice. In looking up the pharmacological literature in relation to the subject, I find that many different preparations of aluminium have been used as antiseptics, particularly the acetate and aceto-tartrate, both of which are freely soluble in water and possess the advantage over the others of being devoid of poison-

ous effects. But, like all our therapeutical investigations, we continually are brought to realize that even among good remedies some are decidedly better than others. It is like the Irishman's whisky. And so it was with solutions of aluminium salts; while good in many ways, their demerits far outweighed their merits. In the first place, the stability of the solution could not be relied upon, and that, in conjunction with other chemical disadvantages, such as throwing down a precipitate of an insoluble base, proved to us that they were not safe agents to employ in daily practice where an unshaken confidence in the evenness of a preparation is absolutely essential. These are among the more important reasons that are given us for introducing an aluminium preparation, perfectly stable when in solution and capable of retaining an evenness of strength, yet possessed of all the advantageous principles which we look for in aluminium. Such a preparation, I unhesitatingly say, we find in alumnol.

Chemically speaking, alumnol is the aluminium salt of a naphthol-sulphionic acid, containing 15 per cent of sulphur in the form of the sulphon group and about 5 per cent of aluminium. It assumes the form of a fine-grained white powder, which may readily be dissolved in cold water to a strength of 40 per cent, this enabling us to make any strength of solution without the danger of separation of the salt from its solvent. It is also soluble in glycerin and hot alcohol. In the latter solvent it exhibits a beautiful blue fluorescence. It is insoluble in ether. Heinz and Liebrecht, its discoverers, tell us that it possesses reducing properties, which they say is evident from its behavior with nitrate of silver, especially when warmed. As a result of this fact alumnol undergoes a change by long exposure to the air, becoming darker. This change, however, does not affect any of its properties and stabilities. Like all the solutions of aluminium salts it has an acid reaction. These salts will precipitate albumin, but differ in this respect from other astringents in that the precipitate immediately redissolves in an excess of albumin. This very behavior of alumnol makes it doubly valuable, enabling it to mix with the fluids of the body rich in albumin and thus enter into the tissue substance. Alumnol will be found to be a most powerful astringent. This property I have tested in many ways, viz: If applied to the tongue in solutions of 0.01 per cent in strength patients have readily become aware of the astringency of the remedy. Much milder solutions, such as 0.0025 to 0.005 in strength, give me like results. I made several experiments on the vascular membranes of animals, and in each case the peculiar astringent property of the alumnol became evident. It was an astringency unlike that of the astringents commonly used by us. In solutions up to 5 per cent in strength there was not the slightest sign of irritation to the membranes experimented upon. Let this suffice for a brief description of the more important chemical features of alumnol; and now a word about its therapy as I know it.

In speaking clinically of alumnol I shall give, in brief, cases in which I found it possessed of advantages above those of other astringents I have used. One of the first cases in which I had an opportunity to use alumnol was a case of epistaxis. Here the epistaxis was due to an erosion of the membrane covering an arterial twig in the cartilaginous septum, and in one or two other varieties much like that form which we so often find associated with cirrhosis of the liver in its early stage, where rupture of the capillaries of the nasal fossæ occur. Here the application to the membrane of a solution of 0.25 to 1 per cent in strength controlled the hæmorrhage in short order. A tamponade saturated with a solution of the same strength is equally efficient, and I have not the slightest doubt that insufflations of powder in the same proportion may be used. I also treated several cases of simple and chronic rhinitis of the form that comes under the observation of the rhinologist almost daily in the following manner, with exceptionally good results: First, I carefully cleansed the passages with a warm solution of

sodium bicarbonate, 1 dram to 1 pint of water. This was followed by the injection of one-fourth per cent solution of alumnol. The cases all showed signs of improvement after a few applications. I also tried the efficiency of alumnol in cases where I had operated for nasal polypi. For several days after the removal of the growths I used an alkaline wash, alternating with injections of a one-half per cent solution of alumnol. In two out of four cases thus treated no recurrence of the trouble followed. The other cases passed from my notice, and hence I am not able to acquaint you with them. In two cases of ozena, one of syphilitic and the other of constitutional origin, both were treated with alumnol with most gratifying results. The nostrils were ordered washed twice or thrice daily with a copious application of sodium bicarbonate, one-half teaspoonful to the ounce of warm water, which was followed by a one-half per cent solution of alumnol. After the last daily washing, a powder containing one-half per cent of alumnol was insufflated. Where abrasions of the mucous membrane were discovered they were covered over with lanolin, containing 5 per cent of alumnol. Often when the incrustations were extensive I applied a cotton wool tamponade, moistened with a very weak solution of alumnol, which I left in the situ from two to three hours, leaving the patient to remove them according to instructions. In these cases the discharges became less offensive, and if we can have such good results I can not praise alumnol too highly. In two cases, when I curetted to remove post-nasal adenoids, I used a mild solution of alumnol, from 1 to 2 per cent, both as a disinfectant and astringent. In one case where the hæmorrhage was excessive the flow was immediately controlled by a 1 per cent solution of alumnol. Not long ago I had occasion to see several cases of syphilis. One was of the bullous variety, with laryngeal complication. The ulceration implicated a large area of both the pharynx and the larynx. In these cases I used douches of alumnol, 1 per cent, after cleansing the parts with an alkaline solution. The antiseptic and healing properties of the alumnol were marked by the fact that the ulcerations healed up in from eight to ten days. In tonsilitis, where the glands are inflamed symmetrically, and which varies much in severity and should not be confounded with suppurative quinsy due to septic causes, often attacking several members of one family, and frequently concomitant with scarlatina and diphtheria. In short-lived outbreaks of so-called infectious sore throat, occurring from bad sanitary surroundings, etc., I have secured very good results from gargles and irrigation with a 2 per cent solution of alumnol.

Alumnol is undoubtedly a nonpoisonous antiseptic and astringent, acting not only superficially but also upon the deeper tissues, owing to its ready diffusibility. The tonsils, we know, are absorbant glands, and their function not improbably may be connected with the absorption of certain elements of these poisonous bacteria which enter the system through this channel. The great advantage of alumnol in this instance seemed to be its power to disinfect the channels without occluding them. This is mainly due to the extreme readiness with which alumnol diffuses itself. I was not long ago told that one bacteriologist who used it found it to be a bactericide of high grade. In most cases of acute and chronic laryngitis, where we are prone to lay much stress on the application of astringent solutions, alumnol in 1 per cent solution gave a good account of itself, especially in those instances where there was a congestion of the vocal bands, the arytenoid cartilages, or interarytenoid folds. I can not conclude this paper without saying a few words about the action of alumnol upon mucous plaques of the tongue of specific origin, in the treatment of which we have not had much to encourage us until lately. I need not dwell upon the many local applications that we have been in the habit of using from time immemorial, but I will say that none gave me such results as alumnol or chromic acid. By vigorously pushing the alumnol application I soon found that it suited patients far better than chromic acid.

In conclusion let me say that in alumnol I find a remedy which is soluble in water, has a penetrating action which makes it specially active, not only against recent inflammatory affections, but against those chronic forms in which infiltrations and induration have occurred. For the latter a higher concentration of the remedy is necessary (from 5 to 10 per cent). Another great advantage is that it can be worked up into various forms, as with glycerin, lanolin, vaseline, gelatin, etc. My short experience with alumnol has been very gratifying. I must ask you to try its efficacy, which I know will not disappoint you.

### DISCUSSION.

Dr. D. BRYSON DELAVAN, New York City. I have been using alumnol for six months and find it a remarkably good astringent, although I have not proved in my own practice all that has been said of it.

### EXHIBITION OF INSTRUMENT FOR FINDING LOST INTUBATION TUBE.

By Dr. J. MOUNT BLEYER, of New York City.

This is my first model of an instrument, which I please to call an electrical probe searcher, for the discovery of a lost intubation tube within the lower air passages. The usefulness of this instrument was practically demonstrated several

months ago upon such a case. This accident has befallen me only once in over 540 of my cases which I had operated on from the year 1886 to 1892. Nevertheless such another may happen again to me and others who operate. The diagnosis of a lost tube can be made by means of this searcher without delay and anxiety, which I believe is worth the price of its cost.

The apparatus consists, as you see, principally of three parts: (1) The battery; (2) the alarm; (3) the bipolar needle-pointed searcher; contained, with their accessories, in a box  $4\frac{1}{2}$  inches by 3 inches, and is complete in itself, requiring no external supplies. The battery is made up of a carbon cell, with zinc electrode,

and is charged with bisulphide of mercury, made ready in a moment's notice by adding a teaspoonful of water to one-fourth teaspoonful of the mercury powder. The alarm is a buzzer. The searcher is a bipolar electrode, with two fine-pointed needles of 1 inch long.

The method in using the instrument is very simple, the probe or searcher being handled in the same manner as a pen. It is held in the right hand, and with the left the skin over the trachea, or in the suspected location of the tube is made tense by an assistant. The needles are thrust in between the rings of the cartilages of the trachea, and explored until the contact is made between the searcher and the tube. Both points of this needle probe usually touch the metal tube at once, and a bridge of contact is formed, which obtains a signal from the buzzer. The location of such a tube is determined beyond a doubt, and preparation for its removal is next in order. This method of searching does not hurt the child.

---

### A CASE OF ELONGATION OF THE EPIGLOTTIS REDUCED BY OPERATIVE MEASURES.

By PRICE BROWN, M. D., of Toronto, Canada.

In the treatment of the case I now report I am much indebted to Dr. Rice, of New York, for a paper read by him last year at the annual meeting of the American Laryngological Association, entitled "The troublesome symptoms caused by the enlargement of the epiglottis, and the advisability of reducing the size of the cartilage by operative measures." I was much impressed by the article when I read it, as I had on several occasions treated patients for laryngeal disease, in whom the epiglottis presented either an abnormal development or some unusual feature in reference to position. In no case, however, up to the time of writing, have I found it advisable to operate, except in the one which I have the honor to report to you to-day. And in this case, owing to its being more one of malposition than malformation, I was obliged to resort to the method which Dr. Rice, at the time of the preparation of his paper, considered inadvisable, namely, the galvano-cautery.

On February 27, 1893, Miss M., æt., 23 years, tall and slight in figure, presented herself for treatment. Family history was not good. Although both parents were living and healthy, yet on the father's side there was extensive tuberculosis. Two of her brothers likewise had died of consumption, between the ages of 20 and 30 years. The patient herself had been delicate from infancy; and according to the statement of her family physician the apex of her left lung had already, upon two distinct occasions, been diseased. During early childhood her respiration had been of a whistling character; and throughout life she had been subject to throat colds, attended by marked hoarseness, sometimes amounting to complete aphonia, and lasting for a period of one or two weeks. One other interesting feature was the difficulty the patient had always experienced in freeing her throat from mucus. Two years prior to consulting me her physician sent her to Colorado Springs for six months. She returned much improved in general health, but with little amelioration of the throat symptoms. When she came for advice she had been free from cold for several weeks. Laryngoscopic examination revealed a healthy larynx, so far as could be seen. The epiglottis, however, was long and narrow, with the end turned up, and it occupied a completely horizontal position. During ordinary respiration the whole of the free end pressed against the posterior wall of the pharynx; while during forcible inspiration or expiration it was raised slightly, seemingly enough to admit the passage of a narrow knife blade. The whole larynx was deeply seated, and it required  $2\frac{1}{4}$  inches from the right angle of the laryngeal probe to reach the tip of the epiglottis. Fortunately the patient was tractable. The manipulation of the parts was tolerably easy; and, as a good view could be obtained, I considered the case a favorable one for operation.

On March 1, after applying a 15 per cent solution of cocaine, I made the first tentative touch with the galvano-cautery, and for the next two days watched care-

fully for pseudo-membranous inflammation or edema, as the possible results of the operation. The reaction, however, was slight, and on the 4th, during forcible breathing, I slipped the galvano-cautery blade between the epiglottis and the post-pharyngeal wall. Then drawing the former forward by means of the instrument so far as to free the pharyngeal surface, I cauterized the central margin and also the left side of the tip. The operation was followed by sloughing and acute congestion of a mild type, but no edema. I operated upon the remaining portions on the 18th and the 29th. Throughout the treatment, simple albolene sprays were made to the throat several times a day. At no time was the reaction very strong; and owing to the effect of the cocaine the operations were not only painless, but the epiglottis itself remained immobile during the cauterizations, enabling the operator to limit, as he might choose, the amount of work done. During the whole course of treatment the deglutition of fluids was not interfered with to any marked degree. Of course solids were interdicted for several days after each application of the galvano-cautery. The shortening of the epiglottis amounted to about one-quarter of an inch, leaving as a result a permanent niche of about half that width.

On April 1, as the patient was in need of general recuperation, I allowed her to return home to a town 100 miles distant. There was still a protruding corner that I did not like, so I arranged for her to come for further treatment later on. Accordingly, she visited my office again on June 6. The epiglottis during the interval had entirely healed, and although she had suffered once or twice from cold this had not, as formerly, been attended by hoarseness. I found, however, as I expected, a little projecting nodule on the left side. This I touched twice with the galvano-cautery at an interval of three days. The healing was more rapid than formerly, and in ten days the young lady was well enough to return home. On final examination before her departure the sloughs had separated, the epiglottis was uniform in length and regular in outline, and although the organ was still and probably ever would be in the horizontal position, the vocal cords could both be distinctly seen, something that was quite impossible previous to the cautery operations. Six weeks later I heard, directly from my patient's mother, that physically much progress had been made, and that the throat itself was now quite well.

In reference to the advisability of using the galvano-cautery in the treatment of cases of this kind, it must be said that the experience gained by the history of one case is not sufficient to establish a rule. Malposition to the extent and in the form described is probably exceedingly rare. It was fortunate that the epiglottis was both narrow and thin, facilitating operation and reducing to a minimum the probability of edema. If, on the other hand, the organ had been broad or thick or hypertrophic, caustic treatment would certainly have been more dangerous in view of possible pseudo-membranous inflammation or edema of the inner surfaces of the larynx. I have, on several occasions, seen severe temporary edema of the palate and uvula following galvano-cautery operations on the tonsils; and if a like result should occur to the ary-epiglottis folds or ventricular bands from similar treatment of a thickened epiglottis, the end would scarcely justify the means. In well selected cases, however, there are several facts in favor of this method of operating which would seem well worth considering. First of all, sufficient time for thorough and careful treatment is in every way essential for a successful result. Then the operations can be performed bit by bit, and by having the patient under daily observation the parts can be kept under perfect control. There is no bleeding to interfere with examinations, and when cocaine of sufficient strength is applied, we have not only immobility of the epiglottis, but likewise freedom from pain during cauterization. To this might be added that the chiseling may be done so perfectly as to challenge comparison with the normal epiglottis.

For cases in which, for various reasons, the galvano-cautery might be unsuitable, I would suggest the construction of a rectangular epiglottome, in which the teeth would merely transfix the epiglottis, without drawing it further into the ring, as in tonsilotomy. The amount cut off by the blade would thus be under the complete control of the operator. If trimming of the margins was still deemed necessary, this could be accomplished by the galvano-cautery after the healing of the primary wound.

## DISCUSSION.

Dr. E. FLETCHER INGALS, Chicago. I have had no experience with the galvano-cautery in such operations as this, nor indeed with any instrument, but the thought suggested itself that if the tissue could be removed by a cutting instrument, such as is suggested in the paper, or a punch forceps, the treatment could be carried out much more expeditiously and perhaps with less danger and discomfort to the patient. The galvano-cautery when used by an experienced person like the author of the paper, is perfectly safe and is of great value, but the resulting reaction is always more than if a simple cutting instrument had been employed; therefore the latter would seem better. I do not know that there are any instruments made for the purpose, but it would be easy to devise one of proper angle with a cutting punch or scissor blade.

Dr. PRICE-BROWN, Toronto. I do not think it would be wise to operate in cases of this kind without you can have the patient remain constantly under your care. Then, if the throat was in that condition, you could treat it as you wished. I know there is danger in using cautery instruments of this sort. Some years ago I used the galvano-cautery in removing the tonsils. After operation the patient went out of the city for a week; when she returned she was completely aphonic, respiration strong, temperature 101°. I examined the throat and found inside of the epiglottis a coating of pseudo-membrane, and I thought at the time it was diphtheria, as there were some cases in the neighborhood. The healing of the throat had gone on continuously; there was no pseudo-membrane in the fauces or larynx, only on the inside of the epiglottis. The vocal cords were congested, also the ventricular bands, and there was a certain amount of edema. I treated the case with inhalations of steam and the patient recovered in a few days, but having that case in mind and believing now that it was traumatic instead of diphtheritic, made me particularly cautious as to the manner in which I operated upon the case I have reported. I think you can operate so that there need not be any danger if you have sufficient care of your patient afterwards; but if not, I think it would be dangerous to operate.

THE SIMPLEST AND MOST PRACTICAL ELECTRIC APPARATUS, ESPECIALLY FOR GALVANO-CAUTERY OPERATIONS.

By ARTHUR G. HOBBS, M. D., of Atlanta, Ga.,

*Member of the American Medical Association and the Pan-American Medical Congress, Ex-President of the American Rhinological Association, Member of the Georgia State Medical Association, and Fellow of the Atlanta Society of Medicine, etc.*

The little apparatus that I am using especially for galvano-cautery operations is the only perfect appliance for that purpose in my knowledge. It has been used in my own and assistants' rooms perhaps a thousand or more times during the last year, and in no instance has it ever failed us or caused us any care or trouble. Indeed, no thought of its presence is ever suggested until it is needed for actual use, quite unlike any of its predecessors, even the best of which required an occasional charging. It is small and compact, contained in a mahogany box 8 inches long, 4 inches thick, and 4 inches deep, and is securely screwed to the wall at a convenient distance from the operator's chair. The wires from an alternating current of 52 volts, the most generally used circuit, particularly in the medium and smaller cities, are brought into the operating room from the street wires and attached at each upper corner of the little box. The conducting wires are similarly attached to the lower corners. The apparatus is now ready to be used for the cautery, the magnet, or for the small incandescent lamp, and it remains always

and ever ready. When the moment for using it arrives it is only necessary, first, to turn a screw, projecting from its nearer surface, with the left hand, while the instrument is held with the right. It thus serves as a gauge for measuring out the exact quantity of electro-motive force in the form of heat, magnet power, or light by modifying the 52 volts, conducted to it from the nearest street transformer, to an alternating current of the fractional number of volts that may be required for the occasion.

As both the force and ampèreage in actual use with this transformer are acquired by induction, and are not in direct contact with the initial current, there can be no possible danger to either the patient or operator, even if the initial wires should by accident come in contact with more powerful wires. The electro-motive force can be gauged between 1 and 16 volts by a screw, and the ampereage is determined by the resistance of the conducting wire. The cost of the electric supply is very small, perhaps \$2 or \$3 per month for all ordinary purposes, including the rent of the meter.

It is quite easy, by modifying the force with a slight turn of the screw, to adapt it to the forehead lamp in ear operations, and to the still smaller lamp used for translucent and direct illumination in the small cavities, as in antrum diagnoses. A much smaller cautery handle than the conventional one is more convenient for actual use, while in addition to this it may be permanently attached to the conducting cord, where it is always at hand, requiring only to change the point to suit the occasion. The larger handles are necessary, however, for the wire loop operations. The needle and a narrow blade are the only cautery points used in my rooms, and in all cases they are made to enter at the most prominent part of the hypertrophied tissue, penetrate down to the bone with white heat, and then withdrawn through the same puncture while the point is hot. In no case is a wholesale destruction of the mucous membrane ever produced by applying the flat surface of the blade to the protruding part. The needle and the narrow blade produce little or no pain when an application of a 10 or 20 per cent solution of cocaine has been locally applied on a cotton probe ten minutes before the operation. The annoying constitutional symptoms, that not infrequently follow even a weak spray, are rarely encountered when a many times stronger solution is applied to a limited area of mucous-membrane surface. Its easy control renders it the most reliable and certain means for making cautery operations on the cornea, because of the small amount of electro-motive force required to heat the fine points used for this purpose. This means of treating corneal ulcers, and, I may also add, of reducing the corneal part of a pterigium, is not only less painful than any other, but the resulting cicatrix is more transparent, provided the cautery is not allowed to touch the healthy cornea. A pterigium will in some cases need no further operative procedure, although it will occasionally be necessary, in addition to the cautery, to sever the vascular supply, without excising any part of the hypertrophied conjunctiva except when it is decidedly thickened. The magnet in general use is constructed for the continuous current, yet it can be charged for the lighter uses with the alternating current. My electrician is now adapting one of these magnets to the alternating current for this apparatus. The electric motors heretofore used for fans and drills were supplied with the continuous current only, but some are now being adapted to the alternating current as applied by the transformer. In addition to these varied purposes that this little apparatus may be called upon to serve, the current that supplies it may be still further utilized before its entrance. For example, it will light two incandescent lamps, and at the same time turn two fans or drills where the motors are suitable, and still supply the transformer with sufficient force. While the volume of the current, or ampereage, is large, the electro-motive force can be reduced sufficiently for therapeutic uses where the alternating current is advisable. In short, it is safe; it is inexpensive;

it is always ready; it is reliable; it exacts no time or attention; it dispenses its force and volume in many practical ways; it occupies but little room and is not unsightly; it does its work perfectly, and if it once gains an entrance to the consultation room of one who resorts to electricity in many of its varied forms it will become a fixture.

---

#### DISCUSSION ON INJUDICIOUS NASAL OPERATIONS.

In opening the discussion Dr. Hobbs said:

If our friends, the gynecologists, have their nymphomaniacs, I think we, too, may have our rhinomaniacs. We have a class (and it is a rapidly increasing class) of patients who consult us with the avowed purpose, to use their own language, "of having their noses burned out." In some respects these two classes are analogous in that the neurotic factor is often present also in our rhinomaniacs, as it is always present in nymphomaniacs. My point is that we may, without much exaggeration, lay the blame of the injudicious, or at least the unnecessary, operation, when we make it under such circumstances, upon the patient himself, unless we place it upon a higher plane, and refuse in all such cases even the pretense of an operation as a placebo or for its moral effect when its necessity is not indicated. While judicious and properly executed rhinal operations have done and are doing an immense amount of good, for this very reason the temptation is increased in many instances to do operations that were better not done, particularly by the younger men just making their entrée into this special line of work. They are loath to allow an opportunity to pass to saw a septum, to drill an exostosis, or to cauterize a protuberance or an enlarged turbinate. The mere suggestion of a septum spur, or a bony protuberance, or an enlarged turbinate is too often deemed a sufficient reason for a surgical procedure, even though no subjective or other objective symptoms may exist. When we are reminded of the large area of nasal mucous membrane its functions should at once be suggested. The nasal space was intended to breathe through, and only secondarily to serve as an olfactory organ. As this great expansion of mucous surface, twice that of the so-called "throat," is intended to perform the important functions of moistening and warming the inspired air, the necessity of its preservation should never be lost sight of. Hence any nasal operation made without reference to the mucous membrane preservation is not only injudicious but harmful, provided the nature of the case does not necessitate its destruction. And again, where no operation can be made without resulting in a large cicatrix, the question may arise, "Would it not be better left undone?" In cases where chromic acid or any other escharotic would seem to be more appropriate on account of the timidity of the patient, or for any other reason, the toxic sequence should always be considered; otherwise the operation may prove to have been an injudicious one. Septum deflections, spurs, and exostoses should always be carefully measured before any operative procedure is resorted to, else a perforation may result that would be worse than the primary condition. The drill is, in my opinion, almost always an injudicious device, for the reason that it necessarily destroys so much mucous membrane and leaves a rough cicatricial surface, although I find myself resorting to it in some cases of prominent exostoses. To attempt to generalize upon the injudicious external operations that are resorted to most frequently in malignant growths, and occasionally in large benign tumors, would require too much of your time, since each case of so serious a nature is a law unto itself and should always be so treated.

## AN IMPROVED MOTOR DYNAMO AND ELECTRICAL CABINET FOR THE ADAPTATION OF THE STREET CURRENT TO OFFICE PRACTICE.

By A. W. DE ROALDES, M. D.,

*Surgeon in Chief of the Eye, Ear, Nose, and Throat Hospital, and in Charge of the Ear, Nose, and Throat Department; Professor of Otology, Rhinology, and Laryngology in the New Orleans Polyclinic; President of the Orleans Parish Medical Society; Fellow of the American Laryngological Association, etc.*

With a view of facilitating the application of electricity for medical and surgical purposes, and at the same time economizing in the cost of using this agent, I have had constructed an improved electrical cabinet, for which I claim, after one year's daily use, the following advantages: Reliability in its action, precision in its application, convenience in the varied uses for which it may be adapted, and economy in the motive power. Although primarily constructed for my needs in the treatment and investigation of diseases of the ear, nose, and throat, it may, without any change in its mechanism, be adapted to all the present requirements for which electricity is used in medicine and surgery.

The cabinet contains arrangements for generating the current required for heating electro-cauteries of all sizes, for operating the drill motor, for lighting up small lamps of all kinds, and for applying the various forms of faradic and galvanic currents. In the application of each of these methods there are new and special features, which render the cabinet of more than ordinary importance. The cabinet very much facilitates the use of the electro-cautery. Instead of using the direct current, as is almost universally the case, an alternating current of low tension is used, as will be explained later, which adds considerably to the life of the cautery point. By means of the rheostat M (fig. 2) the current may be regulated for cauteries of all sizes, and the heating and cooling of the cautery points are regulated by pressure on the foot piece. The drill apparatus also has special features which make it valuable to the surgeon. The capacity of the motor, being one-quarter horse power, will give sufficient power for operating in all kinds of surgical work for which the drill and trephine are adapted, and the working of the motor may be so adjusted that a speed of from 1,500 to 6,000 revolutions per minute may be attained. Of special value is the power of the foot piece to control the operations of the drill, as, by means of an automatic brake, the drill may be instantly started or stopped at the will of the operator by a simple movement of the foot piece. The current for lighting up miniature lamps, such as Vohsen's, Trouvé's, Trautman's, and Heryng's, etc., is controlled by a rheostat, so that lamps of either higher or low resistances may be used. By connecting wires with the binding posts of the cabinet the current may be conveyed to a specially designed "dark room," where it may be controlled by a simple switch. This method I have adopted in my office, and find very convenient in the examination by transillumination for diseases of the maxillary sinuses. The induced currents which may be obtained from the cabinet are six in number: The primary (induced), the secondary, the combined primary and secondary, the alternating primary, the alternating secondary, and the combined primary and secondary alternating. Any one of these currents may be obtained by a movement of the lever of the current selector E (fig. 2), the strength of the current being regulated by means of the lever R in connection with the indicator. The variety of these currents and their range of strength allow a wide latitude for their adaptability in electro-therapy. The galvanic current supplied by the cabinet contains in its circuit a water-rheostat, a milliamperemeter and polarity-changer. By means of a special device the current supplied is protected from the dangerous influence of high currents potentiality from outside wires, which may acci-

dentally fall across the wires which furnish the current to the cabinet. This device also allows of delicate adjustment of the current, so that a strength of from one-tenth of a milliampère to 500 milliampères may be used. The important mechanism of the cabinet is a motor-dynamo, upon the action of which much of the capacity of the cabinet depends. As the name implies, a motor-dynamo is both a motor and a dynamo. Its special function is to transform an available existing condition of direct electrical pressure and volume into another ratio of pressure and volume which may be required for special work. This motor-dynamo was adopted for several reasons, prominent among which is that of obtaining currents of low potential, free from the dangers and cost of using a 110-volt current from the Edison mains direct.

There is a great loss of energy to use a current having a potential of 110 volts in cautery work, when a 5-volt current will do the work, the ratio being 5 to 110; that is, we are wasting  $\frac{105}{110}$  of the total energy passing through the circuit, and utilizing only  $\frac{5}{110}$  in the heating effects upon the cautery. The manner in which we economize energy by means of the dynamo-motor is very simple. By its agency we take, for instance, a current of two ampères at 110 volts pressure, and transform it into mechanical energy (loss about 10 per cent during conversion) or rotary motion similar to that of any ordinary motor, which motion, being transmitted to a shaft carrying another armature of similar construction, but wound differently, enables us to obtain a corresponding reduction in electrical pressure and an increase in the volume of currents flowing in direct proportion to the decrease of this pressure. On this principle, if we take a current of 2 ampères at 110 volts, and reduce this to 5 volts by conversion, we obtain 44 ampères of current at 5 volts, with no greater expenditure of mechanical energy than is represented in the first case, except such losses caused by friction in the parts, self-induction, and eddy currents, which do not exceed 10 per cent for each conversion, making a total of 20 per cent for the whole apparatus. Although in the construction of the motor-dynamo 2 independent armatures, 110 and 5 volts, respectively, are used, yet there is but one pair of field magnets, which envelop both armatures at the same time, which is a saving in the first cost of the apparatus, and likewise economizes the amount of current required to excite them. The side marked A (fig. 3) represents that part of the field magnet covering the motor armatures, and to the right of this is the commutator, by which the Edison current at 110-volt pressure is admitted. This causes the motor to revolve and thus gives the shaft a definite rate of speed. The dynamo armature, being attached to this shaft, is caused to rotate at the same rate of speed as the motor armature, and also in a field, always of the same strength. The dynamo armature, by its rotary speed and power, generates a current of low pressure and great quantity, such as is necessary for cautery work, and this current is delivered to the commutators, B<sup>1</sup>, B<sup>2</sup>, and B<sup>3</sup>, the first two being alternating currents and the last a continuous current, all having the same potential. B<sup>3</sup> therefore gives a continuous current that is available for operating the induction coil with the interrupter in circuit, and from the commutators, B<sup>1</sup> and B<sup>2</sup>, we draw an alternating current which is here used to heat the electro-cauterics, and also to operate the induction coil without the use of the interrupter. It has hitherto been the practice of different makers when constructing dynamos of low-tension currents to generate and make use of those currents flowing in one specific direction called "continuous;" but in this apparatus this process is reversed, a current which alternates about 6,000 times per minute being used. This current, on account of the rapid change of polarity, secures a longer life to the electro-cauterics than when they are heated by a continuous current. It is a well-known fact that the side of any incandescent conductor through which the positive enters will waste away more rapidly than the negative side, and for this reason it is desirable to equalize this action in using the electro-cauterics. The

principal reason, however, for employing the alternating current in this connection is that it enables us to use a commutator having no openings or divisions in its periphery, thereby excluding the possibility of sparking, a point of great importance, as it concerns the life and correct working of one of the vital parts of the apparatus. Sparking is one of the great causes of cutting and destructive wearing of motor and dynamo commutators. For this reason carbon brushes are used throughout the apparatus to the entire exclusion of copper, experience having taught that nothing can equal carbon for this purpose in the present state of our knowledge.

The objection to copper brushes lies in the fact that both the commutators and the brushes being metallic, the current (especially such a heavy current) has a tendency to fuse their surfaces together; as the continual rotation will not permit this, particles are torn off continually, causing what is known as "cutting," which in some cases may become so great as to wear out a new commutator in a few hours. Carbon, being nonmetallic, can not be fused to the rotating commutator, hence its superiority for this purpose. There are 14 brushes used in this apparatus, and were they of copper there would always be difficulty in getting the machine to work smoothly and successfully.

The motor-dynamo of this cabinet is capable of furnishing mechanical energy to the extent of one-quarter horse power. At the end of the shaft F (fig. 3) there is a small apparatus called an "automatic brake," the object of which is to start and stop the power from the motor-dynamo to the belt G, which operates the drill engine at the will of the operator, and is controlled by what is called a "foot piece." The automatic brake consists of five essential parts, marked, respectively, 1, 2, 3, 4, 5 (fig. 3), of which 1 and 2 are electro-magnets; 3 a keeper actuated by them; 4 a sleeve carrying a pulley at one end and the keeper 3 at the other and free to move longitudinally on the shaft F within a limited scope; 5 is a friction cone fastened permanently to the shaft F, and therefore rotating with it. H is an outboard bearing made of hardened and accurately ground tool steel, and is put there for the purpose of steadying the shaft F and to prevent undue side strain from the action of the belt G. J is a hardened and ground steel collar and washer which receives the thrust due to the pressure of the brake magnet (2). On examining the top board of the apparatus (fig. 2) there will be seen a set of three binding posts called "foot piece," and marked 2, 0, 1; they serve for the double purpose of actuating the brake by means of the foot piece and controlling the cautery current, both being operated with the same foot piece.

In this connection the current selector is used. This has eight contacts, marked respectively, "Engine," "Cautery," "Interrupted primary," "Interrupted secondary," "Interrupted primary and secondary," "Alternating primary," "Alternating secondary," "Alternating secondary and primary." The connections are so made that when the handle of the current selector is placed over the word "Engine," the cautery and induction-coil currents will be automatically cut out and can not be used while the engine is in operation. This provision is necessary because the engine may be run at a variable speed by means of the switch K, but these variations would seriously hamper the use of the cauteries and induction coil. To illustrate this, suppose two operators desired to use the engine and cautery at the same time, and let us suppose that the apparatus were so constructed as to permit of such use. If, then, the operator using the engine adjusted the engine at the lowest speed, and the other operator at the same time employed a small cautery, which he brings to the proper degree of heat by means of the switch M—if, now, the first operator desiring to increase the capacity of his drill, increases the speed of his engine by moving the lever at K, the dynamo will simultaneously increase the strength of the current supplied to the electro-cautery, which would probably be at once burned out. When the apparatus is used

for cautery purposes it is requisite that the starting switch K should be at full power on contact 5, and the current selector must be on contact marked "Cautery," and when in this position the foot piece attached to the binding posts 2, 0, 1 will be cut out from operating the brake and the engine belt G, but will simply put the current on or off the cauteries attached to the cautery binding posts. A forward motion of the foot will turn on the current, and a backward motion will cut it off. The action of the foot piece is the same when the selector handle is on contact marked "Engine," but instead of operating the cautery it clutches in or out the brake pulley or shaft F, causing the cable with its drill to rotate or stop instantaneously, according to the will of the operator. In the automatic brake this is accomplished by means of the magnets 1 and 2 (fig. 3). When the current is turned on the magnet 1 it is at the same instant cut off from magnet 2, the result being that the sleeve carrying the pulley 6 is attracted toward magnet 1, and pressed firmly against its surface with a tension of about 50 pounds. When the foot piece is pressed forward the current is cut off from magnet 1 and is transferred to that of 2. This causes the sleeve to press forward, but this time it does not reach the face of magnet 2, being arrested by the pulley 6 coming in contact with the friction cone 5 fastened to the shaft F. This at once causes the pulley to acquire the speed of the shaft, to be again checked when the foot piece is depressed backwards and the keeper 3 is brought in contact with the face of magnet 1. The binding post O is common to both magnets 1 and 2, and therefore there are but three wires in the foot piece.

The current which operates the electro-cauterics does not pass through the foot piece, as this extra resistance would be important to a current having a potential of only 5 volts. Instead of this, the constant current from the dynamo is passed to the foot piece, which operates a magnetic circuit closer, through which the alternating current which heats the cauterics, is passed. When the foot piece is pressed forward the constant current passes to the electro-magnet of the circuit closer and the switch is drawn down, allowing the alternating current to pass to the cautery. When the foot piece is depressed backward, the switch of the circuit closer is released, and the alternating current no longer passes to the cautery. The foot piece thus serves a double purpose, that of controlling the engine and the cautery, and either one may be used according to the position of the current selector E (fig. 2). The cautery can, however, be used at the same time as any of the induction coil currents, and the cautery may still be used when the selector handle is over any of these contacts. The only time that the cautery can not be used is when the engine is used, for the reason already explained.

When the motor dynamo is used to operate the engine, it may be used at any speed within the limits of the rheostat K, but when it is used to operate the cautery, or induction currents, it should be used at full speed, the lever of the rheostat K being on the point 5. The cautery currents are taken from the binding posts marked "Cautery" on the top board of the apparatus, and the faradic currents from the binding posts marked "Faradic." There are six forms of faradic currents generated in this apparatus, all of which are available from the same pair of binding posts, thus avoiding the inconvenience of selecting a new pair of binding posts each time that a different current is required. The current that the operator desires to use is carried to the binding post by means of the lever of the current selector E, which is placed over the contact marked "Primary," "Secondary," etc. The indicator for faradic currents (fig. 2) is operated by the small handle, R, in front of the apparatus, and its object is to indicate the relative immersion of the primary into the secondary coils of the induction coil proper, which is made up of a number of coils so as to permit of the use of simple and complex currents. This indicator serves for all six currents, and, by means of a handle, R, the strength of the current can be very accurately graded to suit the require-

ments of the case. Although the scale is an arbitrary one, still it enables the operator to keep a record of the number of degrees required to give the best results to the patient, and enabling him to use the same strength that was found efficient on a former occasion. P is the rheotome, and is so arranged that it can be adjusted to coarse or fine vibrations by turning the screw of the contact point. X X are oil cups on the motor-dynamo, which require filling regularly. The commutators should be kept clean, and a little vaseline rubbed on the wearing surfaces as a partial lubricant and to deaden the vibrations of the brushes. The motor-dynamo is held down to the bottom of the cabinet by its own weight only, and it rests on six gum washers so as to prevent undue vibrations of the floor and surroundings. The belt G, after leaving the pulley of the motor-dynamo, travels upward and passes over the pulleys marked 1, 2, 3, 4, 5, the pulley 5 being the one attached to the regular S. S. White engine cable and hand piece, the general design of which is shown in the plan (fig. 2). The pulleys 2 and 3 are attached to the sliding arm, and serve the double purpose of taking up the slack of the belt when the arm is slid in or out, thus preserving at all times the same degree of tension in the engine belt G. The engine arm S is capable of turning on a center, from side to side, and the center of motion is so adapted that the belt is always in its radius, and thus never suffers any distortion or strain and can not fall off unless it is loose. Whenever the belt is too loose for proper work the small sliding head, to which the pulley 4 is attached, may be moved forward until the belt has the proper degree of tension. The engine cable head, marked 6, can also be rotated on a common center to the extent of half of an arc of a circle. The cable itself has all the movements commonly given to these devices by the S. S. White Dental Company. V, V, V, V, V are drawers for instruments, electrodes, flexible cords, etc. T is a quick break-switch which cuts all the current from the apparatus when not in use. The engine switch K is also fitted with a quick-breaking attachment, so that as the lever leaves the last contact the circuit is broken with a quick snap, thus preventing the possibility of arcing and its consequent injury to woodwork and the metallic contacts forming part of the circuit. The miniature lamp switch U (fig. 2) receives its current directly from the Edison mains, and is not dependent upon the motor-dynamo for its energy, and the current from this is conveyed to the binding posts marked "Lamp." This lamp circuit is so arranged that the current is drawn from the Edison mains in shunt, and not in series, as is usually done. For this purpose the current from the Edison mains is passed through wire resistance of great length and fastened in coils to the back part of the cabinet. By tapping this wire at different points of the circuit by means of lamp switch U (fig. 2) we obtain a current of sufficient intensity to produce incandescence in the miniature lamp connected with the binding post marked "Lamp" (fig. 2). By means of this shunt system we avoid the sparking incident to using the current when the lamps are placed in series. Z Z are the binding posts, to which are attached the wires leading to the Edison mains. The action and details of the foot piece used in this apparatus are shown in the plan (fig. 2), and require no extended description here. T is the main switch of the galvanic current.

As the tension of the Edison current (110 volts) is too high to make it convenient for the delicate adjustments required for galvanism, and as, moreover, the direct current is not free from a certain element of danger, such as the crossing of the wires with an outside wire carrying a current of high and dangerous potential, I have introduced into the cabinet an arrangement devised by my assistant, Dr. Scheppegrell (New Orleans Medical and Surgical Journal, January, 1893). In this arrangement the direct current is passed through a number of lamps, which divide up the difference of potential, and by means of a volt selector a shunt current is taken from the lamp circuit, varying in strength according to the position of the volt selector. If, for instance, the current be passed through four lamps

of equal resistance the tension of the current will be divided into four equal parts, and by adjusting the lever of the volt selector we may make use of a current of  $27\frac{1}{2}$ , 55,  $82\frac{1}{2}$ , or 110 volts, respectively, thus allowing of more accurate adjustment of the current. As there will be less resistance through the lamp than through the water rheostat and patient, this shunt arrangement forms a safeguard to the patient from extraneous currents. The current, after being adjusted by the volt selector, is regulated by means of a new Bailey rheostat, the strength of the current being shown by the milliamperemeter. A polarity changer is used for reversing the polarity of the electrodes.

In regard to using the motor-dynamo for heating the electro-cauteries it has not only the advantage of convenience and economy over using the Edison current direct, but also the important item of safety. Let us suppose a case where the surgeon has a patient in his chair and is operating on any part of the body with a cautery electrode carrying a 110-volt current, and while doing so a wire in the street, carrying a current of from 500 to 2,000 volts, should become accidentally detached and fall upon the lines leading to the office. This would injure the patient severely, and is an accident that happens quite frequently to all electric-light circuits, the central-station dynamos being sometimes burnt out from this cause.

By the use of the motor-dynamo system the patient is not brought into contact with the Edison circuit direct, and should any outside wire fall on the wires, as described above, it can only result in blowing out fusible plugs by which the motor-dynamo is protected from heavy currents. Another element of danger to be considered lies in the use of a current of such a high potential as 110 volts for cautery work, outside of any consideration of the question of cost. Suppose you have an electrode in the circuit that requires a current of 22 ampères; this will, at a pressure of 110, consume an energy of over 3 horse power. Now, should the cautery suddenly break from any cause, while it is being used, there will be formed a heavy arc, which would destroy all tissue within one-quarter radius of the arc so formed. A current of 22 ampères at 5 volts, such as is supplied by the motor-dynamo, could not give rise to an arc that would in any way be dangerous to the patient. The engine can be operated at from 1,500 to 6,000 revolutions per minute; is adapted for using all kinds of drills and other attachments, and can be stopped within the one-tenth part of a second while making 6,000 revolutions per minute.<sup>1</sup>

#### DISCUSSION.

Dr. E. FLETCHER INGALS, Chicago. I would like to ask Dr. de Roaldes how much his apparatus costs, and I would put the same question to Dr. Hobbs. I would also like to ask Dr. Hobbs if his apparatus can be applied to the powerful currents we have in the larger cities, as well as to those in the smaller ones. I would like to ask Dr. Hobbs whether his instrument allows him to use the current for anything else except the galvano-cautery.

Dr. D. BRYSON DELAVAN, New York City. This is one of the most important subjects that could be brought before us, because one of the newest, and while I fully sympathize with those who have spoken of the expense and extravagance of experimentation in electrical matters, I still think we are advancing in that line and that our trouble in past years has not been thrown away. We seem to have arrived at this basis, viz: That the street current is available for our uses. This has been shown for several years and every season brings up some new and

<sup>1</sup> I take great pleasure in thanking publicly the Messrs. Buchel Bros., of the Buchel Machine Works, New Orleans, who have exercised the greatest mechanical skill and technical knowledge in constructing this apparatus.

improved plan, device, or apparatus by which the street current can be utilized. The great desideratum in regard to it is, first, that we shall be allowed to use it with safety; second, that we shall be able to adapt it to the widest variety of uses; and, third, that in the adaptation of it to this variety of uses we shall not be put to too great expense. The addition of a single department of electricity, the faradic current, for instance, will materially increase the cost of such an apparatus as this, and so with the addition of any other distinct branch. For a man of small means, who has not a very large practice, it becomes a question whether it would pay to try to combine all the uses of electricity in one apparatus, or whether, on the other hand, it would not be more economical to combine several immediate uses in one instrument, perhaps, and supplement that apparatus by other independent instruments. For instance, if we wish to employ a galvanic current for electrolysis or the simple therapeutic use of galvanism, it might be much better to purchase an ordinary galvanic battery and use that, depending upon the street current for other uses. It is extremely difficult to advise others as to what electrical apparatus to purchase.

In my office, while using the street current for lighting, I have an arrangement made by the Edison Company, a series of primary cells, the so-called "Edison-Lalande," which work well, are economical and durable, and on the whole are the most satisfactory of the kind I have ever seen. However, when that happy day comes, and let us hope it is arriving now, that we can convert the street current to all uses at not too great an expense, it will be a desirable thing to do away with all subsidiary apparatus and confine ourselves to one source of power. There is only one serious objection, aside from the expense, to these complicated instruments, and that is every additional complication, every additional connection, switch, etc., put upon a given instrument is liable to increase by so much the possible chance of accident, and unless the instrument is very well constructed and access may be had to the services of a thoroughly competent electrician, the more complicated instruments are not so desirable. The others certainly have a place with residents of the smaller cities and places remote from the centers of electrical information. Although I have the greatest admiration for the instruments that have been presented this morning, it seems to me that as yet the universal electrical apparatus has not been presented. By universal I mean adapted to the largest number of purposes and brought within the means and easy handling of the largest number of men. It is certainly a cheering fact that we have had this morning brought before us two instruments which suggest so much that is valuable and which have gone so far toward solving the large number of difficulties which we encounter. It is to be hoped that before long, from these ideas and those that have gone before, an instrument may be evolved which will answer all purposes for all men.

Dr. A. W. DE ROALDES, New Orleans. I think Dr. Cohen can rest assured that from this time on if he wants to procure either one of the two apparatuses which have been described here, he will have no cause for investing further in electrical instruments that will have to be put aside after spending a great deal of money on them, as has been the experience of all of us for the last ten years. The motor-dynamo and very complete electrical cabinet which I to-day bring before you can not be said to be a cheap apparatus, owing to the fact that a good deal of money was expended on it for experimental work. But now that this experimental stage is over and the mechanical work well defined, this apparatus could, I believe, be duplicated for much less money, say a sum between four and five hundred dollars. Such an outlay, made by a specialist who has a large practice, and consequently reason to make use daily of the different parts of the cabinet, will, in the long run, be found to be a profitable investment. The cost of running is so insignificant that I have found the electrical company which supplies the direct current for the motor unwilling to furnish me with a special meter. I

had, therefore, to submit to a minimum tariff of \$3 a month, which, however, includes the current for the illumination of several rooms. Of course my apparatus is much more costly than the one described by Dr. Hobbs; but remember also that, besides a galvano-cautery, it embodies, in a neat and compact cabinet, a drill, as well as all the different forms of currents for medical use and for electrolytic work. In addition, with the ingenious little apparatus of our colleague, Doctor Hobbs, there is a considerable loss of energy, even when using only a current of 52 volts. This has been obviated in my cabinet by means of the motor-dynamo, as already explained. When considering the cost of the apparatus one must also consider the wide range of electrical applications which it furnishes in a neat, compact, reliable, and economical (as to running expense) form. You have first an electrical drill as a part of the apparatus, with such an arrangement as no other electrical drill offers, an automatic brake that will allow you to start or stop the drill almost instantaneously (within ten seconds). Its power is equal to one-quarter horse, which is sufficient to do any kind of surgical work. The galvano-cautery is so arranged as to heat at will the smallest cauteries for ear work to the heaviest knives, the control of the current being transferred from the handle to the foot piece. You have in addition all the varieties of the faradic current, with an improved scale of measurement, and a finely graduated galvanic current available for medical use or for electrolytic purposes. This apparatus with its different combinations will allow you to utilize the current of the street for any purpose in medicine and surgery, and while it was originally designed solely for my special work, it is practical for the general surgeon. If the different parts contained in this cabinet were to be obtained as separate electrical apparatuses I doubt very much whether the aggregate expenditure of money would not be as great. The running expenses would certainly be greater. As to the reliability of this motor-dynamo and electrical cabinet I will only say that the guaranty of one year has expired without having to call on the expert electrical engineer who built it. The apparatus was so well constructed that at no time in eighteen months of daily use has there been a single part out of order. The only attention it requires is on the part of my office nurse, who keeps the cups properly supplied with oil.

Dr. Arthur Hobbs, Atlanta, Ga., in closing the discussion, said:

Yes. It will charge a magnet; it will give a light to the small incandescent lamps, either for direct or translucent purposes, which could not be gotten directly from the street wire. Electrolysis can not be obtained from an alternating current; it would neither reduce the electro-motive force nor the ampèreage sufficiently for this purpose. The cost of the cautery through this little apparatus is practically nothing; possibly as much as 10 cents per month. The only cost is that of the wire, which you would already have in your office for light and power before attaching the transformer. I am not sure of the cost of this transformer. My electrician has, however, assured me that it will not cost over \$30 or \$35. The only transformers now in use are the three in my own and assistant's rooms. I think \$35 will be its probable cost. I would not sell mine for \$1,000 if I could not duplicate them. The current must be alternating. The one best adapted to it is the 52-volt, but the 120-volt will do, or even the high power of 500 volts may be used by first distributing the force through five or ten lamps and motors before the current is carried through the transformer, provided it is the alternating current and the magnet and motors are properly adapted to it.

## SOME OF THE THROAT CONDITIONS OBSERVED IN GOUTY SUBJECTS.

By SOLOMON SOLIS-COHEN, M. D.,

*Professor of Clinical Medicine and Applied Therapeutics in the Philadelphia Polyclinic; one of the Physicians to the Philadelphia Hospital, etc.*

The term "gouty subject," as used in this paper, has perhaps a somewhat wider range of meaning than can strictly be ascribed to it, if only those are to be termed gouty who have suffered with articular inflammation, or who exhibit characteristic deposits. In this country, at least, a much larger number of persons suffer with other than articular manifestations of the uric-acid diathesis, their symptoms being varied, and often obscure, until the cause is discovered upon examination of the urine, which shows more or less constantly an excess of urates and uric acid, and often contains calcium oxalate and excess of phosphates. In both classes of patients the upper air passages are frequently affected, and while the gouty diathesis can not be affirmed to be the sole cause of the local manifestations, it doubtless acts as both a predisposing and a modifying influence.

Harrison Allen<sup>1</sup> has sharply discriminated between gouty sore throat and the lithemic throat, and has reported a number of instances of the former condition. He has also given such references to literature as are of value in this connection. I am not inclined, however, possibly because of a more limited experience, to make equally sharp distinction with Allen. Sir William Roberts<sup>2</sup> has well shown the important difference between uric-acid gravel and gout, the offending materials in the latter case being deposited in combination as urates in the true interior of the body, while in the former they are deposited as uric acid, on a doubling of the external integuments; yet even he admits that the underlying conditions are virtually the same. Reasoning upon clinical analogy and without direct histologic evidence, it seems to me that cases of the class treated of in this communication occupy what may be termed a middle position, the phenomena depending in large part upon irritation due to offending materials in the circulation, but in less part upon actual deposition in the fibrous tissues.

A large number of cases would have to be recorded in detail by different observers, and a careful analysis made, before characteristic signs of throat gout could be laid down. Reference should be made to the valuable studies of Hinkle,<sup>3</sup> with whom, however, I can not agree in assuming that the cases reported by Ingals as instances of rheumatic sore throat were of a gouty nature. This paper does not aim to present more than the general results of personal observation extending over a number of years, but necessarily dealing with a limited number of cases. The condition, depending as it does upon a permanent error of metabolism, is probably in most, if not in all, instances a chronic one, with a tendency to paroxysmal exacerbation, under the influence of extrinsic or intrinsic exciting causes. Among the most frequent of such exciting causes are exposure to cold or to wet and indiscretion in diet.

The frequent dependence of chronic sore throat on diathesis has been recognized by systematic writers. Thus, concerning the causation of "chronic catarrhal sore throat," J. Solis-Cohen says:<sup>4</sup>

The disease is not usually a sequel of acute sore throat, but becomes gradually developed without attracting much attention. It may exist with any diathesis. Sometimes it is a mere manifestation of disorder in the intestinal tract.

And again, concerning treatment, he remarks:

As this affection may coëxist with a variety of diatheses, the systemic treatment will vary in accordance with the constitutional requirements. Alkaline laxatives are usually indicated.

Attention being as a rule first directed to gouty sore throat during a paroxysm, its diathetic origin may be overlooked; and the case may be mistaken for one of the ordinary forms of acute inflammation. Inflammation, however, is not a necessary feature of the disease, and in my own experience the most prominent symptoms have been sensory; pains and perverted sensations of various kinds being referred to circumscribed regions, often described as "spots," in which no structural alteration adequate to explain the symptoms can be discovered. In one of the most marked cases that has come under my observation, that of a married lady, some 45 years of age, who is of a gouty family and has gouty deposits in the finger joints, the spot most frequently pointed out as the seat of the discomfort is in the left pharyngeal angle just behind the free border of the soft palate. This, however, is not the only location of pain, which is variously described as stinging, burning, pressing, or like that caused by the presence of a foreign body. Sometimes the discomfort is referred to the neighborhood of the epiglottis; sometimes to the side or the base of the tongue; sometimes to several points at once. These spots are often painfully sensitive to the touch, and can thus be accurately localized. The patient has an idiosyncrasy to cocaine, and it could not therefore be determined whether or not the application of this drug would abolish the localization of pain. Similar localization is found in many, but not in all cases, and usually fails when cocaine has been applied, though this is not invariable. I have been of the opinion that when sensitiveness persisted after application of cocaine the trouble was deep-seated in the fibrous structures. In some cases pain is referred to a part apparently unrelated with the one touched, but the association is constant, and the impression left upon the mind of the observer is that the error is in the reference, few persons being able to describe accurately the exact seat of a sensation in the throat.

Sometimes, and more especially during an acute paroxysm, visible alterations of structure are manifested at the painful spots. The most usual appearances are the presence of dilated blood vessels; veins or capillaries, several of which may cross one another at such a spot. Sometimes a single large blood vessel is found; sometimes there is a dusky coloration of the mucous membrane; sometimes an enlarged and reddened follicle. Often, however, there is no apparent difference from the surrounding membrane, which sometimes presents general congestion, and sometimes nothing out of the ordinary. When congestion exists it may be patchy or uniform. Usually the coloration resembles that of corned beef; sometimes it is dusky red, or even purplish. In the larynx, the epiglottis and the arytenoid eminences seem the favorite seats of morbid sensation, the former usually exhibiting a network of dilated vessels resembling a veil, the latter a slight tumefaction and reddening. In two cases, in young men, I have seen what appeared to be inflammation limited to the neighborhood of one crico-arytenoid joint. There was pain on respiration and phonation, vaguely referred to this region. I have frequently seen similar appearances at the inception of an attack of acute rheumatic tonsilitis. In some cases there is during the more acute stages a characteristic diffuse laryngitis, much resembling, and perhaps identical with, the form described by J. Solis-Cohen<sup>1</sup> as occurring in young adults addicted to overfeeding and the abuse of condiments. In these subjects the tongue is red or reddish-brown, thick, puffy, with prominent papillæ, with a somewhat thick coating at the base, extending in streaks

---

<sup>1</sup> Diseases of the Throat and Nasal Passages. Second edition, p. 474. New York, 1879.

toward the tip. The mucous membrane of the pharynx, palate, and palatine folds is relaxed, puffy, and usually congested. The mucous membrane of the larynx, and especially of the arytenoid eminences, and of the ary-epiglottic folds, is similarly puffy and always congested; the vocal bands are pink or red, the color being deepest at their posterior insertions. A pellet of mucus is usually adherent to the meso-arytenoid fold, and as a rule mucus is found in other portions of the larynx as well. The voice is hoarse; the hoarseness is greatest in the morning and after meals. There is a constant desire to clear the throat of mucus; the expectoration is greatest in the morning. The patients often complain of a feeling of fatigue after slight use of the voice. This sensation of tiredness may be referred to the larynx or to the pharynx. The conditions described may pass off in a few days; they may persist for ten days or a week; or they may merge with the chronic symptoms.

In the pharynx, the tonsillar and peri-tonsillar structures and the angles of junction of the posterior and lateral walls have seemed to be most frequently affected. There may be enlarged glands. The tongue and its glands are often involved. The mucous membrane of the tongue or of the cheeks sometimes presents whitish patches of cornified epithelium (*leukoplakia buccalis*). When the distressing sensations are referred to the rhino-pharynx, Luschka's tonsil may be tumefied and reddened. In young patients the pharynx and larynx are often covered with grayish, tenacious mucus; in those past middle life the pharyngeal and palatal membrane is often dry and pale, exhibiting a network of enlarged and tortuous vessels, or mottled with livid patches.

Relaxation of the palate is common, and in some subjects paroxysms of nasal obstruction, with or without coryza, are met with. This was noticeably the case in a man aged 54 years, a neurasthenic, with gouty deposits in the drum membrane, and in whom at other times nasal respiration was perfectly free; there being no structural deformity that would impede the passage of air. During these paroxysms of obstruction the turbinates would be puffy and pasty looking; the posterior wall of the pharynx would be apparently bulged forward, and the soft palate would likewise appear puffy and pale. There would be an annoying sensation of a foreign body between the throat and the nose, and efforts at hawking, though ineffectual, would be continually repeated. Examination would not reveal sufficient accumulation of mucus in this region to account for the sensation. In this case the hard and soft palate were occupied almost constantly with a network of large, bluish vessels, which during the paroxysms referred to became still more tortuous and darker in color. Upon one occasion I proposed scarification, but the patient—perhaps wisely—would not consent. In some cases tubal catarrh exists and sensations of distress are referred to the ear. In a case similar to the one just cited, pain was referred to a point marked externally by pressing the finger just behind the angle of the jaw, whence it radiated into the ear. In a few cases spasmodic choking in swallowing and spasmodic obstruction of respiration, laryngeal and bronchial, have been observed. In one case an attack almost resembling croup was followed by an outbreak of articular gout.

The diagnosis in these cases, while suggested by local appearances and symptoms such as have been described, depends upon recognition of the constitutional condition, and can not be affirmed in the absence of the ordinary evidences of such constitutional disorder. Urinalysis gives the most important evidence in cases in which there has been no articular inflammation or deposit.

Local treatment is palliative only and it should be sedative and protective; irritating and stimulating applications are counter-indicated. Astringents may be cautiously employed during exacerbations. For this purpose I have found the glycerole of tannin applied by cotton wad, or a spray of zinc sulpho-carbolate in rose-water (5 grains to the ounce), the most useful. Cocaine is badly

borne by some patients, inducing spasmodic phenomena. When well borne it is useful to relieve pain. Applications of fluid extract or concentrated infusion of coca will at times be feasible and useful in cases in which the alkaloid can not be employed. I have likewise found aconitine oleate (2 per cent in oleic acid, freshly made and flavored with oil of almond) a useful analgesic application. Menthol (from 2 to 5 per cent in liquid petrolatum, as a spray; from 5 to 10 per cent topically by cotton wad) is occasionally of great service; in some cases, however, it can not be tolerated. Bromoform (topically by cotton wad) has given relief in one or two cases in which other applications were inadmissible. In chronic cases solution of iodine and carbolic acid in glycerin (of each 1 grain to the ounce, with  $1\frac{1}{2}$  grains of potassium iodide to facilitate solution) applied to the spots of painful sensation, or brushed over the entire pharyngeal wall, is of service. Before making any of these topical applications, whether in acute or chronic cases, the parts should be cleansed by an alkaline and aromatic spray. In quite acute pharyngitis a gargle of hot milk and borax, or of plain hot water, or hot alkaline solution, often gives great relief. Guaiac is likewise of benefit. In acute laryngitis alkaline sprays, followed by the inhalation of the vapor of hot water impregnated with benzoin and paregoric, are useful. For permanent relief, of greater or less degree, dependence must be placed on dietetic, hygienic, and medicinal measures appropriate to the uric acid diathesis. It is unnecessary to detail these here, but I would like to record my favorable experience in this connection with strontium bromide.

#### ILLUSTRATIVE CASES.

*Case 1.*—Mrs. L., aged 50, for some years has had attacks of tingling and sensations as of the presence of dust (hardly intense enough to suggest the presence of a feather) at the left side of the throat. When this feeling is experienced she is forced to cough, and with the cough comes a sensation of strangling. The cough is short, at first sharp, afterwards, with the strangling sensation, muffled. There is never any expectoration. The pharyngeal mucous membrane is irregularly reddened and thickened, and there are a number of prominent follicles, surrounded by reddish whorls of dilated vessels. The larynx is diffusely congested, the color being deepest over the arytenoid eminences. There is no mucus in the larynx or pharynx; Luschka's tonsil is reddened and prominent. There is no turbinate engorgement, and though the septum is slightly deflected to the left, nose breathing is, and has always been, free. The patient has frequent attacks of shooting pains in the finger joints and about the knees. There are gouty changes in the last joints of the ring and middle fingers of the left hand. For some years she has been compelled to rise at night to urinate. The urine at times is burning. The patient belongs to a family of good liver, some of whom have had articular gout. She is very stout and has a sallow and flushed complexion. Urinalysis showed the presence of free uric acid, as well as excess of urates and calcium oxalate. The specific gravity was high. No sugar or albumin was found. A spray of liquid petrolatum, with 5 per cent of menthol and 2 per cent of cocaine, was prescribed to be used three times a day and whenever the unpleasant sensations were experienced. The diet was carefully regulated, outdoor exercise directed, and strontium bromide given in doses of thirty grains three times a day before meals. Under this treatment the patient rapidly improved, and up to date (ten months) there has been no return of the paroxysms.

*Case 2.*—Mr. M., aged 52, of full habit, sallow and flushed complexion, complains of ringing in the ears, of a pain darting from the ear to the throat, and from the throat to the ear, sometimes felt externally behind the angle of the jaw. There is a constant desire to clear the throat, but very little mucus is ejected. The nose feels stuffed up. At times there is a burning sensation referred to a definite spot in the pharynx. The palate is relaxed and covered with a network of bluish vessels. There are a number of enlarged follicles in the pharynx, which is irregularly streaked with red and bluish patches; between these the intervening membrane is quite white. A sensitive spot is found just beneath one of the enlarged follicles on the posterior wall. The patient recognizes this as the seat of the burning. There is considerable tumefaction of the posterior wall of the pharynx toward the lateral angles. The septum is slightly bent, though not suffi-

ciently to obstruct respiration, and the lower and middle turbinates are red and swollen. The tongue is heavily coated, and the papillæ are prominent. Some accumulation of thick, tenacious mucus is seen in the vault of the pharynx. The mouths of the Eustachian tubes are widely open, and the whole structure appears much larger than normal. No mucus is detected in the Eustachian tube and air enters it freely. The drum membranes are opaque and show gouty deposits. The patient is a dyspeptic; his urine shows excess of urates, calcium oxalate, no albumin, no sugar. A spray of menthol and cocaine in liquid petrolatum was prescribed, but the strength had to be reduced to 2 per cent of menthol. The rhino-pharynx was wiped clean every morning with a cotton wad, saturated with a 2 per cent solution of cocaine. Counter-irritation over the mastoid processes with tincture of iodine was from time to time employed, and iodine, carbolic acid, and glycerin solution applied twice a week by a cotton wad to the nasal passages. Regulation of diet and antilithic treatment internally were kept up. The patient slowly improved and was dismissed from treatment in the course of three months. He had become largely rid of his distressing symptoms, though not altogether of the roaring in the ears. Once in a while he returns for local treatment, which seems to give him relief.

*Case 3.*—Mr. C. H., aged 30, a traveling salesman, for a year or more has had frequent attacks of hoarseness, with a feeling of "rawness" in the throat. There is no pain in swallowing. The attacks last about a week. The intervals of freedom vary from a month to six weeks. The present attack has lasted longer than usual—some ten days. There is a slight, hacking cough and a desire to clear the throat. There is no trouble in breathing, nasal or otherwise. The tongue is heavily coated, the pharynx congested in streaks, the larynx slightly congested, the epiglottis flaccid, the arytenoid eminences puffy. There is pain referred to the upper part of the chest, but no physical sign of pulmonary lesion. The heart is normal. The patient is a very stout man. He uses tobacco largely and drinks beer moderately. He is a hearty eater and a gourmet. The urine is 1.034 in specific gravity, of acid reaction, and contains urates, uric acid, and calcium oxalate in excess. Diet was regulated. A solution containing strontium bromide and strontium lactate, 15 grains each, was given in water, before meals. The patient was ordered to drink hot water one hour before meals. Zinc sulpho-carbolate spray was applied locally. Relief was reported in four days. There has been no return of discomfort as yet.

---

#### DISCUSSION.

Dr. JAMES E. LOGAN, Kansas City, Mo. I was very much interested in the paper, as I have given the subject some consideration within the last few years, and especially the relation the general practitioner should bear toward the throat specialist. I have found some cases very interesting in their nature that were only remediable through agents of general medication. Where I had tried local treatment, where examination revealed very little, if any, active inflammation in the pharyngeal cavity, there were possibly some little inflammatory points referable to the follicles of the tongue, especially where they come in contact with the anterior and posterior faucial pillars. That is one of the most aggravating of the painful points these patients complain of. There is another, to me, pathognomonic symptom in these cases; that is, a complaint of a tired sensation in the throat, and especially is this tired feeling experienced after a little excitement. In all these cases I have made the urinary analysis the Doctor speaks of and found the condition as he represents it. Not more than five weeks ago I had an elderly lady in my office who gave every evidence of this condition from the urinary analysis. I found her very apprehensive. The pain was so excessive and aggravated that she could hardly realize that it was other than the most malignant type of disease. I assured her this was not the case, and put her on an antiseptic treatment and a mild astringent—the sulphate of copper—for its moral effect more than anything else. The patient was relieved in a little while. She had had one or two previous attacks, but not so severe, and she and her family got the idea that it was some malignant disease. I reassured her on this point, and found the case remediable through medicinal and not through local means.

Dr. J. H. LOWMAN, Cleveland. I think the subject of paræsthesia of the pharynx and larynx is interesting, because instances of that kind do come under one's observation where it is impossible to make a diagnosis. The question of paræsthesia of the pharynx in tuberculosis and paræsthesia of the larynx in gouty conditions may be distinguished by the color perhaps, but they run into one another so closely sometimes it is difficult to make a distinction. Not infrequently I have seen people who have complained of pains in the limbs and of a sensation as of a foreign body in the throat, where I could find nothing in the throat to explain the phenomena and could find absolutely nothing in the constitution to explain it, but have been able to trace it to tuberculosis later, the paræsthesia, by some accident in the career of the individual, manifesting itself first. It strikes me that paræsthesia in the gouty subject may be the same; the system is ready, and by some accident it appears. I remember an instance where the individual had this congestion and disease of the pharynx with occasional pains in the limbs and paræsthetic sensations, and then he had gouty urine, etc., and after any little excess of eating or drinking he would have most intense edema of the uvula; it would become as large as his thumb, and this would last from one to three days, then the throat would go back to the normal condition again. The edema of the uvula would be so great that it would have to be clipped; no remedies would have any effect upon it. I think the diagnosis is very difficult in paræsthesia.

Dr. S. SOLIS-COHEN, Philadelphia. Of course I did not go into the great subject of the diagnosis of paræsthesia; I recognize its difficulty. Nor would I be understood to imply that all cases of paræsthesia of the pharynx or larynx are gouty. I simply recorded my experience with a number of cases as being related with a uric-acid diathesis, and have confessed my inability to make a positive diagnosis by local signs in affirming that it can only be made by a recognition of the constitutional condition.

---

### A CASE OF ANGIOMA OF THE NASAL SEPTUM.

By FREDERICK C. COBB, M. D.,

*Assistant Physician for Diseases of the Throat at the Massachusetts General Hospital and Physician to the Throat Department of the Boston Dispensary.*

The patient, Lizzie B., 15 years of age, came to the Out-Patient Throat Department of the Massachusetts General Hospital in October, 1892, complaining of obstruction of the right nostril and epistaxis from the same side. The duration of these symptoms was about six months. There had been no sneezing, and only occasionally a yellow, thick discharge from that nostril. She was anæmic, always subject to headaches, and exhausted by the least exertion. Her previous history, with the exception of an attack of scarlet fever six years ago, was negative. Examination of the anterior nares showed them to be normal on the left side. On the right side the nostril was wider, the turbinates slightly atrophic. Hanging from the septum by a thin pedicle inserted near the junction of the skin and mucous membrane, above the end of the lower turbinated bone, was a small growth divided into two lobes by a constriction about its middle. It was soft to the probe, moved backward and forward on inspiration and expiration, but was not seen to pulsate. At its lowest portion were a few small, black blood clots. The posterior nares, pharynx, and larynx were normal. With the aid of Hooper's snare and écraseur the growth was removed with very slight hæmorrhage. The base was not cauterized, the patient was given an alkaline wash, and returned two or three times until the site of the pedicle was completely healed, which occurred in about ten days.

She was examined in August, 1893, and has had no recurrence. The growth was submitted to Dr. Whitney, the pathologist to the hospital, and the following report

was received from him: "Growth with large vascular sinuses with more or less round cells about; cavernous angioma." In looking over the literature of nasal angiomata one is struck by the lack of pathological accuracy shown by the reporters of cases. If we inquire what is the structure of angioma, we find, according to Bosworth, that it is composed almost entirely of blood vessels held together by a slight network of connective tissue. Sutton, Ziegler, Birch-Hirschfeld, and other pathologists agree with this definition. Now, if the reported cases of angiomata be judged by their pathological examinations, we shall find, I think, that a pure angioma of the nose is very rare. The importance of pathological accuracy will be evident when we remember that the prognosis may depend upon it.

Sarcomata and epitheliomata may contain small portions of nearly pure angiomatous tissue, and if such portions alone are removed for examination they may lead to very erroneous conclusions. The cases reported are those of Verneuil,<sup>1</sup> Wagner,<sup>2</sup> Steinbrügge,<sup>3</sup> Seiler,<sup>4</sup> Richet,<sup>5</sup> and <sup>15</sup> Roe,<sup>6</sup> Jarvis,<sup>7</sup> Vanderpoel,<sup>8</sup> Burckhardt,<sup>9</sup> Nelaton,<sup>10</sup> Huguier,<sup>11</sup> Panas,<sup>12</sup> Guyon,<sup>13</sup> Dumenil,<sup>14</sup> Delavan,<sup>16</sup> Luc,<sup>17</sup> and Bellows.<sup>18</sup> There were in all twenty-one cases.

There was no microscopical examination in 7 cases, viz: Those reported by Dumesnil, Verneuil, Seiler, Panas, Guyon, Vanderpoel, and Burckhardt. In 5 cases the growths contain myxomatous tissue and are not therefore pure angiomata. These cases were reported, 2 by Wagner, 2 by Luc, and 1 by Delavan. Three cases, those of Richet, Huguier, and 1 of Nelaton's reported by Beuf, were probably fibromata rather than angiomata. We have then left the cases of Richet (reported by Bazy), Roe, Jarvis, Steinbrügge, and Nelaton's other case.

Roe's case was, by microscopical examination, an angioma, but it subsequently degenerated into an angio-sarcoma. Nelaton and Richet's pathological description is not characteristic enough to class their tumors among the angiomata, while in the case of Jarvis no pathological description, but only the diagnosis was given by the microscopist. Steinbrügge's case was evidently an hypertrophy. Bellows's case was, by the microscopical examination, a pure angioma.

As a further proof of the rarity of this affection, I would say that in an examination of 7,429 cases in the Massachusetts General Hospital records I have found no other case.

With regard to the symptoms the only two of importance are hæmorrhage from and occlusion of one nostril. In all the reported cases a mere examination of the growth with probe or finger caused extensive hæmorrhage.

As regards prognosis it is evident from Roe's case that a pure angioma may degenerate into a malignant growth.

The diagnosis of pure angiomata can only be made by careful microscopical examination. In the treatment of these growths we are met with less difficulty since all the recent authors seem to consider the snare, if used slowly, as the safest instrument. The length of time to be consumed in removal should depend upon the thickness of the pedicle. In Roe's case three hours were consumed in removal of the growth, the hæmorrhage being very slight. Jarvis and Luc got no hæmorrhage with slow snaring, but considerable from more rapid use of the instrument. The former used his own snare and *écraseur*, the latter the galvano-cautery wire. In my own case I attribute the slight hæmorrhage to the thickness of the pedicle.

---

#### DISCUSSION.

Dr. JOHN N. MACKENZIE, Baltimore. I thoroughly agree with what Dr. Cobb has said in regard to the rarity of these tumors. They seem to me to be extremely uncommon. In my experience I have only seen one case of true cavernous angioma; that was a case which occurred last year at my clinic, at the Johns Hopkins Hospital. It was operated upon by one of my assistants with the snare, and considerable hæmorrhage followed. It is singular, but comparatively few of our anatomists are intimately acquainted with the structure of the nasal mucous membrane, that is to say, its cavernous structure; in a great many works on anatomy it is entirely overlooked. In the transition stage of simple inflammation to hypertrophy men have mistaken the large network of cavernous spaces for cavernous angioma and I think a number of the cases in literature are none other than portions of the hypertrophied membrane in the stage which represents the transition period from simple inflammation to the hypertrophic stage. There is one condition, too, that may be mistaken for true angioma, a condition I described some years ago before the Laryngological Association, namely, a pendulous prolapsed condition of the turbinated bodies. The turbinated body sometimes assumes a pendulous form and may even hang out from the exterior of the vestibule, presenting all the appearance of a true angioma, and that might very readily be mistaken for an angiomatous tumor.

Dr. F. C. COBB, Boston. I agree with what Dr. Mackenzie has said, but in this individual case the tumor grew from the wall of the septum itself and contained no glands or any other signs of hypertrophy; the pedicle was very thin and small.

---

#### AN INTERESTING CASE OF MYXO-SARCOMA, WITH GENERAL SARCOMATOUS INFILTRATION.

By CHARLES S. RICHARDSON, M. D.

During the early part of October, 1892, there came under my observation a child, 5 years of age, presenting quite an interesting clinical history. This child had previously been under the care of Dr. Bayne, who referred him to me. The patient was born to parents of unusually good health and free from any hereditary physical defects or vice. The child was strong and apparently in perfect health until the end of his second year. At this time his parents noticed that he sniffled and that his nasal breathing was somewhat impaired. This difficult nasal breathing became slowly but progressively worse, and was followed by a train of symptoms due to imperfect nasal respiration. He became restless at night; snored and caught his breath; would wake up crying, as though frightened; would breathe with his mouth open; and on awakening in the morning would be cross and irritable. About six months before coming under my care the parents

noticed that his voice was muffled and had lost nearly all its nasal quality. The child now began to lose flesh, showing but a slight desire for food. A growth now developed upon right side of neck, and it was also observed that something was protruding from the left nasal cavity. Discharge from nasal cavity was thin and watery, never sanious, nor was there ever any free bleeding. Shortly before consulting Dr. Bayne dysphagia was added to the child's already pitiable condition. At this time the inability to ingest food was confined to solids, liquids being taken with some degree of ease. Dr. Bayne removed the mass protruding from the nose, and then referred the parents to me.

On presentation he was noted to be a well-formed boy of average height; body and face extremely emaciated; nasal breathing entirely annulled; oral breathing distressingly loud and unpleasant. He was very weak; voice almost absent and unintelligible; was drowsy, and if held quiet for a few moments passed into a deep sleep. Externally his nose was well formed and showed no deformity. On the right side of neck there was a tumor of about 3 centimetres in diameter. The mother stated that for about three days the child had found it almost impossible to ingest food, either liquid or solid, and she feared that he would starve if something were not done immediately. I found her statement to be absolutely correct, as the child could not swallow water when offered. Both nasal cavities were filled with a grayish white mass which protruded slightly. The mouth was in a horribly offensive condition; the lips were fissured and covered with dry crusts and the teeth with sordes. The tongue was dry, horny, and deeply congested along its free borders. The hard palate was covered with dark brown deposit and the soft palate pushed forward until the uvula rested on the center of the dorsum of the tongue. The whole pharynx was filled up with a dirty grayish white mass that extended to the larynx below and pushed forward the soft palate until it extended well into the mouth. This mass was more or less lobulated and its lower borders were hornified. I appointed the next day for operation.

Suspecting that the growth was malignant, I prepared for considerable hæmorrhage. I operated without the use of an anæsthetic. Dr. Balloch assisted me. I removed the mass from the nose, first with the cold snare, attended with only moderate bleeding. The pharynx was cleared with the finger and post-nasal forceps. The hæmorrhage from the whole operation was much less than ordinarily attends the removal of post-adenoid hypertrophies.

The child was greatly improved by the operation and gained strength and flesh very rapidly. On the fourth day after the operation I observed a large mass of mottled grayish black tissue in the left nasal cavity, which I removed with the snare. This mass was slightly necrotic, and I supposed it was a piece that I detached and failed to remove during my first operation. Four days later, on the child reporting, I found the cavity again filled out with a mass similar to the one removed at the previous sitting. This mass was about 3 centimetres long by about 1 centimetre in diameter; softer and more pultaceous than the first tissue removed. Bleeding was also more active. I was now firmly convinced that the growth was a myxo-sarcoma. In four days there was a greater reproduction, extending even into the pharynx. On this day Dr. Balloch confirmed my diagnosis by telling me that the tissue originally removed was from a myxo-sarcoma. I now consulted with Dr. Bayne as to the advisability of doing a more formidable operation. The excision of the superior maxilla met with his approval and the day was appointed for its removal. The child's condition on the day of the operation, although only six days since my last interference, was quite as bad as previous to any operative interference whatever. The attachment of this growth seemed to be about midway of the under surface of the middle turbinated bone. With the assistance of Drs. Bayne, Van Rennselear, and Luce, I did Billroth's operation for resection of the superior maxilla. Chloroform was administered. An incision

was made from the root of the nose, extending in the median line to its top through the soft tissues and into the nasal cavity, upon the side to be operated upon. From the root of the nose an incision was carried outward to the malar prominence. In making this latter incision care was taken in carrying the knife along the margin of the orbit to avoid the infra-orbital foramen from fear of dividing the artery issuing from this canal and thereby cause troublesome hæmorrhage. An incision parallel to the second incision was carried from the ala of the left nasal cavity to the border of the masseter muscle. The nasal bones were now disarticulated and the flap containing the left nasal bone was rapidly separated from the left maxilla and thrown outward. Bleeding vessels were taken up as divided and consequently only a very slight amount of blood was lost. The whole nasal cavity was now exposed and filling out this space was seen the same character of growth that had been so often removed. The growth was traced under the middle turbinated bone, from whence it seemed to have its origin by a broad base. The body of the superior maxilla was now separated by sawing outward, in the lines of the skin incisions, and after the mass had been separated it was pried out of its position and turned outward upon the cheek. As the growth now could be seen to involve the antrum, probably secondarily rather than primarily, I decided to remove the bony mass entirely, and therefore separated it from the pterygoid process. A part of the palate bone and the pterygoid process were torn away by the forceps. The whole cavity was now free of growth. Rough edges were curetted away and the cavity having been packed with iodoform gauze, the skin flap was brought into position and carefully united. Hæmorrhage was quite free, but to no alarming degree. The patient bore the operation well and rapidly recovered from the shock. There was no bleeding after reaction set in. The patient was in good spirits and quite hungry the next morning and had no fever. On the fourth day the iodoform dressing was removed, coming away quite clean, and new gauze introduced. On the fifth day all stitches were removed and union found to be perfect. On the seventh day the gauze was finally removed. There was no fever throughout. There was only a slight difference to be noticed in the prominence of the two sides of the face. At the end of the third week, as the child seemed to be in a perfect condition, I discontinued my visits. Five weeks later the mother requested me to see the child on account of the rapid increase in size of the tumor on the right side of the neck, and, if possible, to relieve the child from the great pain that this rapid increase in size had occasioned. The growth had now assumed enormous proportions and filled out the whole left cervical region, extending from the mastoid to the clavicle. I also noticed a smaller growth on the left side, just above the clavicle. During the following week new growths appeared in lateral walls of the pharynx and in left cervical region; there was no recurrence in nasal cavity. Four months after the operation the child died from inanition and exhaustion.

In looking over the histories of some 60 cases of nasal and naso-pharyngeal sarcomata, many of the latter no doubt having their origin in the nasal cavity, I find several that correspond in their description very much to the case above given. In these extensive growths I find that the patients were quite young, but none so young as the case herein presented. Rapid reproduction is common in sarcomatous tissue, but the rapidity of regrowth in this case was of a startling nature. To have all evidences of a growth removed in one day, and within six days thereafter to have it nearly reproduced in its original magnitude, is sufficient to excite the admiration of any pathologist. We have all been taught that hæmorrhage is quite a necessary attendant upon malignancy; especially is this stated in regard to sarcoma. It therefore appeared to me to be quite remarkable that this little one had had no trouble of this character, and that the various operative procedures were attended with so little bleeding. The micro-pathological

find was that of a most typical and exquisite myxo-sarcoma, and even here we have an interesting feature to call to your attention. As you will observe, here and there disseminated throughout this mass of tissue are single fibers of striated muscular tissue. The section which shows these muscular fibers in the most pronounced manner was obtained from a mass removed from the nasal cavity.

There are several points in connection with the operative interference that require consideration. In a case of this character where operative interference was not so immediately demanded to relieve the urgent symptoms, I think it would be wise to first ascertain the character of the growth before resorting to any instrumental interference. It seems that all interference, excepting that it be of radical character, intensifies the rapidity of growth and its malignancy. One well knowing the nature of the growth can consider, from its seat and attachment, whether it is possible to remove it in its entirety and more thoroughly by the snare, or whether it will be necessary to resort to one of the more formidable operations. Growths so extensive as the one outlined above should, if any operation is attempted, be dealt with in a most liberal manner. The reason the above case was not so treated at first was on account of the desperate condition of the child and the necessity for immediate action. A positive diagnosis could not be made out from its clinical history alone. It is also a question whether even the latter operation would have benefited this patient, as no doubt a general sarcomatous infiltration had already set in when he was first brought under my observation.

---

#### SARCOMA OF THE NASO-PHARYNX, WITH REPORT OF A CASE.

By J. E. LOGAN, M. D., of Kansas City, Mo.

J. N. T., age 44 years, a teacher by profession, consulted me in June, 1888, presenting the following history: Up to the age of 40 had always been a strong, healthy man; in the autumn of 1884 he was taken with a severe attack of typhoid fever, which lasted for many weeks, convalescence being very slow. Upon recovery, or shortly thereafter, he noticed what he termed "quite a fullness in the upper part of the throat," which was accompanied by considerable secretion of saliva and some interference in breathing, especially noticeable when in a recumbent position. This condition grew steadily worse, so much so that within a few months he was unable to breathe through the nose, could scarcely talk, and had frequent sensations of impending suffocation. He applied to a local practitioner, who examined his throat and found a tumor large enough to be easily seen, low down in the pharynx. The general health of the patient had now become greatly impaired, the discharges being very profuse and extremely offensive. The physician, not feeling himself able to cope with such a disease, and not being properly equipped to perform the necessary operation, referred the man to a surgeon in our city. As nearly as I have been able to learn by questioning the patient, this gentleman pronounced the growth a fibroid tumor. He at once removed it, and dismissed the patient, leading him to think or at least to hope himself cured. His general health did improve immediately. He breathed easily, and his appetite returned. This improvement, however, was of short duration. Very soon there was a return, and a rapid and aggravated return, of all of his former symptoms. In six weeks from the time of the operation he was utterly unable to breathe through the nostrils, the discharges were fetid, the hæmorrhages were frequent, and for the first time there was considerable pain, referable principally to the left ear. The surgeon again examined him, and found to his great surprise that the growth had returned. He now gave it a more careful examination, though not, I believe, with a microscope, and pronounced it malignant. A tonic course was

prescribed in order to build up the patient's general health before venturing upon a second operation; but the tumor grew with such rapidity that he was forced to remove it while the man was still in a very weakened condition. During all this time there were no glandular complications and comparatively little pain. The second growth was removed by means of a wire *écraseur*, and the patient reports the operation as very bloody, though I am inclined to think that a very little blood would impress him greatly. He rallied from this second operation very slowly, but for five months he enjoyed comparative immunity from his trouble.

At the expiration of this period the old symptoms reappeared, but in a modified form. The discharges were profuse and offensive, but the difficulty in breathing was not so marked. Profiting by past experience, he lost no time in having the new growth removed; but his promptness availed him little. The tumor again appeared in a few weeks and another operation became necessary. This went on until he had submitted to nine such operations. The frequency of these discouraged him greatly, and he finally concluded to seek the aid of a throat specialist. He applied to my friend, Dr. Schauffler, for advice in the selection of a physician, and Dr. Schauffler brought him to me for treatment. Examination of the case revealed the presence of a tumor perhaps twice as large as a partridge egg, situated for the most part upon the roof of the pharynx, with attachments along the post-pharyngeal wall for the distance of one-quarter to half an inch. Digital examination provoked profuse hæmorrhage. The tumor appeared slightly lobulated and was firmly attached to a large base. The patient's general health was much much below par. He was somewhat cachectic and was suffering considerable pain in the left ear and in the back of the head. Profiting by the experience of the other operator, I concluded to remove the tumor by another method. Tying back the soft palate, I applied a 10 per cent solution of cocaine to the growth and the surrounding tissue until complete anæsthesia was established. My first step in the operation was to cut the tumor into three sections with galvano-cautery knife, continuing the cautery from the surface to the base. My object in so doing was to cut off the blood supply as much as possible. I next insinuated a curved, flat knife under one section and removed it without much difficulty. Very little hæmorrhage attended this operation. I applied persulphate of iron to the cauterized base and sent the patient back to the hospital. I saw him each day, but applied no treatment except a warm spray of Dobell's solution. A week from the day I first operated he came back to my office, and I proceeded to remove the remainder of the growth. Upon examination I found this had been much reduced; in fact but one section of it remained, the other having sloughed away and been expectorated by the patient. The remaining portion was hanging by a few attachments to the base. I introduced my curved knife as before and easily severed the growth. The hæmorrhage was hardly perceptible. I continued to keep the patient in the hospital for a few days, using no application save the warm Dobell spray. At the end of two weeks the surface had completely healed; so perfectly healed that scarcely any induration could be detected by digital examination. I had the growth examined by several most competent pathologists, and all agreed in pronouncing it a round-cell sarcoma. The patient immediately began to improve in health under the administration of tonics and outdoor exercise, and is living to-day, as fine a specimen of manhood as one would care to see. Repeated examinations have failed to reveal the slightest evidence of a return. One of my neighboring medical friends saw him just a few days since and carefully examined him, with negative results.

So far as I have been able to find in looking over the literature of this particular subject, this is about the twentieth case on record and about the second of well-defined recovery. Some are reported as recovering from the operation and continuing in good health during the period of observation, such observations

admitted by the operators to be of limited duration. Dr. Bosworth's case is one of well-known recovery, since the patient is to-day within the limits of this beautiful city, with no intimation of trouble from the disease. The case reported by Dr. Lincoln was probably one of recovery, but his period of observation was too short to enable him to say certainly that there was no return. We see enough after looking into this matter to prove that sarcoma of the naso-pharynx is a very rare disease, and in a large majority of cases is fatal. Just why a few of these cases have recovered while the others have died we can not, of course, explain. But might it not be well to observe that of all the cases operated upon those removed by the simplest means have shown the greatest tendency to recover? In writing upon this subject Dr. Bosworth says in his monograph in Wood's Medical and Surgical Monographs, Vol. XI, p. 256:

Various operations were resorted to in these cases, such as the galvano-cautery, curette, the spoon, and the cold snare manipulated through the natural passages, while some of the cases were subjected to radical operations, such as excision of the jaw, etc. There certainly seems to be something of consideration in the fact that the only successful case was cured by the use of the cold snare operated by the natural passages; and moreover that in this case the use of the galvano-cautery was attended with most unfortunate effect, indicating here also, as in the nasal cavity, that this disease is to be treated with great gentleness and any danger of injuring neighboring parts avoided.

The truth of his last proposition I think beyond question, but the opinion which Bosworth expresses of the galvano-cautery is scarcely borne out by the facts presented by my case nor by those in the one reported by Dr. Lincoln. The inflammatory reaction following my operation was inconsiderable—so slight indeed that the Eustachian tubes did not even show any signs of participation, which they would naturally have done had there been any such condition. Had the growth been of such a size as to have made necessary the application of the cautery for an indefinite period, I should probably have resorted to more rapid means; but when one is able to accurately define its outlines in the vault and can apply the galvano-cautery without danger of injury to other tissue, it seems to me to be the most simple and effective measure.

---

#### DISCUSSION.

Dr. JOHN O. ROE, Rochester, N. Y. One case of myxo-sarcoma of the nasal cavity came under my observation about six years ago. I was requested by a physician in Cayuga, N. Y., to go there and remove a growth from the nose of an old lady. I found a lady about 65 years of age, with the nose so dilated and face so disfigured as to have a frog-shaped appearance. What annoyed her the most was the projection of so much of this tumor into the throat as to nearly choke her. I was not prepared to operate upon such a formidable growth, but with the instruments I took with me I succeeded in removing the greater portion of it. I passed a wire loop down through the nostril along one side of the growth, brought it out of the mouth, and passed it up along the other side of the growth. Then, with the finger in the mouth, I engaged the greater portion of the mass in the loop and removed it. The amount removed nearly filled an ounce quinine bottle. I did not remove the whole of it, however, as the base was attached to the ethmoid and the middle turbinated bones, but the patient was very much relieved by this operation. As she was much reduced in strength and quite anæmic, we built her up as best we could, so that in a few weeks she was able to come to Rochester, when I proceeded to remove the base of the growth as thoroughly as possible. She stood the operation very well, but in a few days she sank and died from asthenia. The

portion I removed first showed it to be a myxoma; but the latter portion that I removed, the base, showed it to be a sarcoma, so that very likely it started with the outer portion a myxoma and the base a sarcoma.

Dr. E. FLETCHER INGALS, Chicago. I am interested in this matter, having seen a number of cases of malignant growth of the nose, though I can not now state whether they were sarcomas or epitheliomas. I now recall four cases. One, in a lad twelve or thirteen years old, was shown by careful microscopical examination to be a mixed sarcoma, and partially fibrous, but with enough of it of the sarcomatous element to ensure its malignancy. In that case the reaction following the use of the galvano-cautery increased the rapidity of growth, and I obtained much better results from operations with the knife, snare, or forceps. The growth was carefully removed two or three times, and the boy lived for at least two years how much longer I do not know, as he passed from my observation. I once saw such a tumor in a gentleman of advanced age, where the nose was so full, the patient so debilitated, and his age so great that I could not conscientiously advise any operation. He lived but a short time. In another case upon which I operated two or three times with the snare and cautery, the patient was considerably relieved and lived for five or six months. I saw such a tumor recently in a gentleman 63 years of age. The right nasal cavity was distended by the growth, there was abnormal prominence of the right cheek, and considerable protrusion of the right eyeball. The patient suffered greatly from pain through the right side of the head. Some part of this growth, which had been termed a polypus, had been removed a little while before. He and his family were very anxious to have another operation. Believing that extensive operations for malignant growths in this locality in aged people are seldom justifiable, I did not decide upon a surgical procedure until after consultation with Dr. Senn and weighing all the circumstances in the patient's history. Removal of the superior maxilla was considered inadvisable in a man of his age, so I decided to remove the growth by the cold wire snare and a sharp spoon. The patient was given ether and the cold wire snare introduced in a manner I thought likely to remove the attachments of the tumor without causing much bleeding. I was unable to ascertain the exact attachments of the tumor before operating, therefore I passed a special canula through the upper and outer part of the nasal cavity, keeping it as far to the right as possible, and brought it into the naso-pharynx. Through this I passed a small catheter, the end of which was caught by forceps and brought out of the mouth; through this I passed one end of a steel wire 3 to 4 feet long, bringing it out through the nostril. Another catheter was passed in beside the lower outer part of growth and the other end of the steel wire was pushed through this until it came out of the nose. The ends of the wire projecting from the nose were then drawn upon and at the same time the catheters were removed and the loop drawn in through the mouth up to the outer side of the tumor, as the upper part of the tumor was likely to be adherent. Another catheter was passed through the canula, through which I had returned the end of the first wire; the end of the catheter was brought out of the mouth and the end of a second long wire passed through it and out of the nose. Another catheter was then introduced and brought out the mouth as high up as possible on the left of the tumor and through it the other end of the second wire was passed; the catheters were then withdrawn, the wires pulled out, and the loop passed in at the mouth and inclosed the upper attachment of the tumor.

I put a snare on each of the wires and cut off the growth, which proved softer than I had anticipated. There was practically no bleeding. My reason for using the snares was that I expected much bleeding when the growth was attacked and felt that if I could get out the major part of it without much loss of blood I could then curette rapidly and pack the nose to stop the hæmorrhage. I pulled out the

piece which had been separated with the forceps and then scooped out the remainder of the growth rapidly with a sharp spoon. There was but little hæmorrhage. The patient was a large man, which made it easy after the removal of part of the growth to introduce my little finger into the nasal cavity. I could feel the granular surface of the malignant tissue, and I scraped it out until the walls of the antrum and the vault of the nasal cavity were perfectly smooth. The floor of the orbit having been absorbed I could feel the under surface of the eyeball, separated from my finger only by a granular tissue which could not easily be scraped away and was finally concluded to be adipose tissue. The tumor seemed to have been as thoroughly removed as it could have been if I had removed the superior maxilla. The next morning the temperature ran up to  $103^{\circ}$ , and for seven or eight days the patient complained of pain in the eye, which was much swollen. A large diffused induration just back of the angle of the jaw was also swollen during this time. About the eighth day the fever went down, the swelling subsided, the pulse became nearly natural, and the patient became comfortable; but before another day had passed he had a chill, the temperature rose to about  $104^{\circ}$ , and twenty-four hours later he became paralyzed on one side; an extravasation of blood into the brain had occurred, from which he died three or four days later.

Dr. C. W. RICHARDSON, Washington. The consensus of opinion seems to be in favor of the milder operations. Of course, when they are attended with the best results in a nasal case such should be the course to pursue, and such would be the course I would pursue in many of these cases if the growth was small and did not infiltrate neighboring tissues, but as the general surgeon deals with sarcomatous infiltration in other portions of the body in the most liberal manner, so it seems to me that in many of these cases of sarcomatous infiltrations of the nose and pharyngeal cavities that have resulted fatally, when the growth was small if they had been dealt with in a more liberal manner and the growth removed in its entirety they would probably have resulted differently. In the case I reported I do not think anything was to be done except in the most generous manner. The case was a good one for such operation if there had not been the probability of secondary infiltration. It had already involved the antrum and the posterior portion of the antral cavity. To have attempted to remove this with snares would have been useless, as five or six operations previous to removing the maxilla proved. Of course in a case of that kind where the patient is in such an emaciated condition, and in fact demanding interference to save the life if possible, the particular operation I did was the one that should be done. The rapid reproduction of the case was something very startling. Within four days after the removal of the tissue, both with snare and forceps, the patient returned and I found a great mass filling out the left nasal cavity. I could hardly believe it was a reproduction until after I had got my snare on it and tore it away. When I removed it the posterior portion was somewhat necrotic; that was evidently where the growth had formerly been removed, and tissue above it had been pushed down as reproduced. There was reproduction again in four days, which was very remarkable, and each time the growth was removed the tissue was of a more malignant character. I did not refer very much to the gland that was situated on the right side; the growth was on the left. When I operated upon the case the patient seemed to be in a pretty fair condition, and I was in favor of removing that gland, or rather the tumor, but the gentleman who was with me in the case seemed to think it was an enlarged gland. Within three months that growth had assumed enormous proportions. Dr. Bayne saw the case before me and thought he detected fluctuation, and opened it, thinking it was an abscess. I removed some of the tissue from this opening and found it to be sarcomatous. Before the child died the whole left side was filled out the same as on the right and the condition was one of the most marked general sarcomatous infiltration that I had ever seen.

Dr. JAMES E. LOGAN, Kansas City, Mo. About three years ago I had sent to me a case of sarcoma of the nasal cavity, which was so complicated that the patient was completely depressed and very anæmic. The sarcomatous infiltration extended into the eyeball socket and upper eyelid, so much so that the lid was thickened and protruded out from the man's face. From my previous experience in operations upon the superior maxillary, I decided to remove this growth, which I found situated upon the turbinated bone, filling almost the entire antrum, with the galvano-cautery by piecemeal, if I could get the patient to live long enough. I was satisfied the infiltration was so great the patient would die anyway. I removed about one-third of this growth. This patient while in the army had received a chest wound in the right side just above the nipple. He began to sink rapidly after the operation and died from hæmorrhage from the lungs. I made an autopsy and found that this sarcomatous infiltration had gone to the seat of the wound he received some thirty years previously, and from that center had extended over the whole lung surface. As regards the use of the galvano-cautery in these cases, so far as I have been able to see, operative procedures of a severe type have never been followed by evidences of even partial recovery, and in these cases the only operative procedure I would recommend would be a partial removal, at repeated sittings. I do not think anything other than the galvano-cautery or the cold snare should be used under any circumstances; that the results in these cases do not warrant a more thorough operation.

---

#### DISCUSSION ON TREATMENT OF HAY FEVER.

Dr. D. BRYSON DELAVAN, New York City. No greater task could be imposed upon one than to open a discussion upon the subject of hay fever. It is desirable, however, to obtain the sense of this meeting on the treatment of hay fever, and I hope that the discussion will be strictly confined to this department. There are two conflicting opinions regarding hay fever. One is that it is essentially a local condition; on the other hand, it is held by a far greater number that however much local influence may have to do with its production there is, broadly speaking, in the majority of cases at least, an underlying condition of some sort which tends to the production of this disease. Accepting the latter view, it is necessary that the treatment should be conducted in accordance with it. If it is conceded that there are general causes underlying hay fever, then reliance can not be entirely placed upon the treatment of local conditions. The general as well as the local state of the patient must be attended to. It is necessary therefore, in order to treat hay fever successfully, to look into the general well being of the patient and find whether he is suffering from lithemia, malaria, or any serious disorder of the heart, lungs, or kidneys, and to investigate the condition of his digestive tract. These, or any other general or diathetic states which could contribute to the local trouble, must, as far as possible, be improved.

The local treatment of hay fever may be broadly summed up under two distinct heads. Under the first plan are used various heroic therapeutic and surgical measures. Under the second are employed general therapeutic measures which are not heroic, the chief object of which is to subdue local irritation, and there are also surgical means which have exactly this same end in view. I believe that where conditions exist in the nose which contribute directly to the irritation of the nasal passages, such for instance as distinct organic occlusion of the nose, then surgical means may be of great use. On the other hand, nasal surgery in this department has often been carried too far. It is extremely unwise to interfere in a case in which we can discover no good cause for interference, simply because the patient desires to be cauterized or to have a spicula of bone removed which

he supposes is there. Where there is not present a condition which distinctly calls for surgical interference it is wrong to advise the removal of apparent obstructions, and to practice the use of the galvano-cautery as often applied to the nasal mucous membrane in such cases. It may be unnecessary to state here that wholesale destruction of the nasal mucous membrane is not a good means of curing the disease, yet there are some who, in a case of hay fever, will destroy it far and wide, by means of caustics or the galvano-cautery.

With regard to the use of cocaine; every good thing seems to have its negative side. Thus, the most valuable of drugs, opium for instance, may become the most dangerous; and so it is with cocaine. This drug is doubtless a great blessing to persons suffering from hay fever. Its indiscriminate use, however, in this disease is productive of serious evils; indeed, in these cases cocaine improperly used will do vastly more harm than good, and I would like to go on record as distinctly and vigorously opposing its indiscriminate use in these hyperesthetic patients.

To recapitulate: If the discussion be confined to a few of the points herewith raised we shall have enough to do. I would like to call attention especially to the question of the recognition and treatment of coëxisting conditions. I would also call attention to the abuse of surgical interference and to the proper and improper use of cocaine. The discussion should include the best means of treatment; that is, the means which are the most practical, the least theoretical, and most successful. The discussion seems opportune here in view of the fact that this meeting represents such a wide diversity both of territory, experience, and thought.

Dr. PRICE-BROWN, Toronto. I suppose I am particularly qualified to speak on hay fever, as I have been subject to it for the last ten years. I do not know in my personal history that I have suffered organically any other way; I do not know that my system has been deteriorated; I do not know that my kidneys, or lungs, or organs generally have been at all out of order, but I know that periodically, about the middle of August, I have an attack of this disease. I may say, however, that before I ever had hay fever, frequently with the slightest cold I suffered from closure of the nasal passages to a certain extent. I would find the greatest difficulty in breathing through the nose in cold weather, and this finally developed into an attack of hay fever. For two or three years I did nothing special for it; then I used a little cocaine; but four years ago the attack I had was most intense. I remember that it did not seem as if I had the power of thinking or feeling anything, except the intense sensibility produced by the disease, and I determined to operate upon myself, if I could find the part of the nasal cavity where the thing originated. I felt the indications in the back part of the left naris. After sneezing about one hundred times I sprayed the left naris with a 10 per cent solution of cocaine, and passed a probe into the passage. I found at the back end of what I assumed was the inferior turbinated bone a sensitive spot, with another about the middle of the passage. I then passed the cautery blade to the posterior spot and turned on the electricity and singed it; then to the next spot and singed that. The result was that for the rest of that year my paroxysms of hay fever were not so severe. The following year the trouble commenced in the back of the right nostril, and when most intense I operated in the same way. I might say in passing, that I have had many cases of hay fever under treatment at different times; and one of the prominent symptoms has been exceeding irritation of the palate, particularly the uvula, the patient desiring to scratch the uvula and rub his tongue over it. The result is there is great elongation of this organ. The following year I amputated half of my uvula, which resulted in great benefit. Last year my attack of hay fever was not very severe. This year it has been less than ever, and I have had no operation. It came on about the 24th, instead of the 14th, and I had no hay fever of any account until I started from Toronto, but on

my first night in the hot, dusty car coming south the attack became intense. I got alumnol the moment I heard of it. The treatment I generally use is a light solution of cocaine, giving it myself. I use the cocaine first, and afterwards menthol in albolene. It seems to me the action of menthol in from 5 to 10 or even 20 grains to the ounce has the effect of lengthening the action of the cocaine. Latterly I use menthol more than I do anything else in my cases; this year I personally used no cocaine whatever. I find it more beneficial to apply the menthol to the throat, and have the patient breathe in through the mouth and out through the nose. In regard to any occlusion producing hay fever, I mentioned a case this morning where the columnar cartilage pressing against the wall of the nostril caused hay fever, and the removal of that cartilage removed the hay fever. From the effect that alumnol has had upon me to-day I think it will prove a good thing, and I shall try it in future.

Dr. JOHN O. ROE, Rochester, N. Y. In every case of hay fever there is more or less disease of the nasal mucous membrane, and the more I see of hay fever the more I am convinced of the correctness of this assertion. I have yet to see a patient in whom disease of some portion of the nasal mucous membrane does not exist, and when I hear a case reported in which the patient suffered intensely from hay fever but without any local disease in the nose I think that the doctor is in error and did not discover the local lesion, perhaps on account of making only a cursory examination. When we consider that the nasal mucous membrane in adults covers a region of about 26 square inches it is not surprising that disease may lurk in some portions and remain there undiscovered unless a most thorough examination is made. Hay fever may be considered a neurosis (pardon me for an allusion to the neurotic theory), but we have a great many neurotic people who do not have hay fever, and there are a great many people who have a great deal of disease in the nose who do not have hay fever; but when a person who is intensely neurotic has a great deal of trouble with his nose he is quite sure to have hay fever. There are a great many, as in Dr. Brown's own case, who have fever when there is apparently no neurotic element, and in such cases the disease is, I believe, as much a local disease as any disease can well be. Disease in the nose that may be the seat of the irritation is not necessarily confined to any one region, as it has been believed to be confined to the region of the inferior turbinated bodies, either the anterior or posterior end. The part that I have found to be most sensitive in these cases is the nasal septum, and this undue sensitiveness has been usually excited by an intermittent or constant pressure of the turbinated bodies. The exciting cause of these neurotic conditions I believe to be in nearly all cases intranasal pressure, either from intermittent or constant contact between the different portions of the interior of the nose. It is, however, not necessary for this pressure to exist between the turbinated bodies and the septum, for it may exist between the turbinated bodies themselves or the inferior turbinated body and the floor of the nose. In the latter instances the extreme sensitiveness is confined to these bodies.

The galvano-cautery in the treatment of these cases is frequently the most serviceable agent we have, but there are many conditions of the nose in which its use is not advisable. It is useful in vascular turgescence, but can not be employed to advantage in firm hypertrophy or osseous excrescences. It is usually not advisable to institute treatment during the attack, although in some instances the abnormal conditions in the nose are emphasized during the attack and should be attended to at that time.

The beneficial effect of local treatment can not be better illustrated than by the case of a young lady whom I treated last summer one year ago. She was about twenty-three years of age, distinctly neurotic and neurasthenic, and her mother was also neurotic. She had suffered from hay fever severely for seven years, and was willing to have anything and everything done that would relieve her of this distress-

ing complaint. As it was so near the time of her attack I advised her to have the nostril in which she had the most difficulty treated, as she was unable to go through the necessary treatment for the removal of the difficulty from both sides at the same time. There was pressure of both the inferior and middle turbinated bodies against the septum. This I relieved and carefully treated the nose. The result was that she passed through the summer without any trouble in this her left nostril, while in the right nostril, which had not been treated, she suffered from hay fever quite severely, although, the left nostril being free, respiration remained unobstructed and she did not suffer the distress experienced when both nostrils were completely blocked up. Later in the season, after the hay-fever period had passed, I treated the other side carefully, and she has passed through the hay-fever season this year without any disturbance from hay fever.

In all cases of hay fever, more or less constitutional treatment is advisable, as the local disturbance has a marked effect in lowering the tone of the system, independently of the neurotic trouble with which it is frequently associated. The tonics proposed by Dr. Mackenzie are excellent and I have found them of great service. One thing that is of importance is nutriment to build up the system, and one of the best nutriments I have found to be eggs. By breaking an egg into a glass and having the patient swallow it whole he will take from five to ten eggs, or even twenty, a day. Many patients will be very much improved and their attacks somewhat modified by increasing the resistance of the system to local irritation, or frequently by the employment of a sedative that will abolish to a great degree the response of the nervous system to the local irritation, but in addition to this there is in all cases some localized disease, which should be found and carefully treated. Therefore, however much you treat the person generally and build up his nervous system, or however much you may improve the condition of the vascular system, you must attend to the local condition in the nose, be it ever so severe or ever so slight, if you wish to relieve your patient positively and permanently from hay fever.

Dr. S. S. KOSER, Williamsport, Pa. I am glad to note on the part of this section the deprecation of the free and undue use of cocaine. It was only a week ago that a pharmacist of my city mentioned to me that he had regularly several customers for cocaine, and added that he was quite sure that the habit was first contracted in all of them from using the tablet at home, that the market is now flooded with, for these nasal cases. I believe the position taken this afternoon in the matter of prescribing cocaine, not permitting the patient to use it at home, is wise. It is a terrible thing to be the means of establishing cocaine inebriety in any case. In connection with this discussion I wish to call attention to a couple of articles that have done me good service as temporizing agents in mitigating the severity of hay fever. One is terebene. I have certainly found it quite valuable as a mitigating agent. I would also like to call attention to an old remedy, but one that has not been referred to in this discussion, and that is the inhalation of a strong solution of carbolic acid, camphor, and chloroform, in the proportion of about a dram of the crystals of the acid and  $1\frac{1}{2}$  drams of the camphor to 2 or 3 drams of chloroform, used in a smelling bottle. In fact, these cases come to us at such a stage that I rather prefer to palliate them first. I do not believe it is good surgery to rush into an operation on the nose when the engorgement is so great. That is, I do not believe proper conditions exist for good surgical repair. I would rather say it is good practice to first palliate the case and watch for one of those opportunities which the gentleman from Toronto (Dr. Price-Brown) referred to as the conditions present prior to developing hay-fever symptoms, and to operate on the turbinates at some time other than during that attack. Preëminently, in my experience, the operation that does the most good and which is more permanent is to gently clip the lower ends of the turbinated bone. This, in my hands,

yields the most lasting benefit, and I have frequently preceded an operation with the use of the cautery, so that there might be less tendency to hæmorrhage following the operation itself. The point, then, I wish to make is that in my experience I have had better results in operative procedures if I deferred the operation until the intervals of the attack. I believe, then, that the permanent results are better, the parts will heal kindlier, and in all respects will do our patient a greater good.

Dr. JAMES E. LOGAN, Kansas City, Mo. I wish to confirm Dr. Roe's experience in hay fever. Living in a country where hay fever is prevalent, I have seen a great many cases, but I have yet to see a case uncomplicated with hypertrophic rhinitis or rhinitis in some form. I read an article before one of our medical societies in 1886 in which I made the statement that I did not believe hay fever could exist without a previously existing rhinitis of some form, and after years of experience I am willing to support that statement to a considerable extent, for I have never seen a case where there has not been some such trouble, either from a deflected septum, exostosis, hypertrophic rhinitis, or some disease where there was a soil in which this idiosyncrasy was produced.

The treatment I have used for the last few years has been the cautery. I begin the cauterizations about a week previous to the first attack and continue them at intervals through the period of hay fever, and by continuing these cauterizations after the period has passed, relieving whatever condition, mechanical or otherwise, that existed there, and in succeeding year continuing a mild course of cauterization through the period of hay fever, I have relieved quite a number. I have recorded some cases of very pronounced recovery in this respect.

A lawyer who has an office next to mine, who was a constant sufferer for sixteen years, suffering the tortures of death almost from hay fever, and who had travelled the world over seeking relief, is a standing monument of the efficacy of the treatment of hay fever as I have suggested it. To-day he has no trouble whatever from it, and there are a number of cases of a similar nature. The neurotic tendency, which I believe exists in nearly every one of these cases, whether it be perceptible to the physician or the patient, is a latent element which must be corrected by medicinal means preceding the hay fever period. Beginning a week previous to the attack, I administer a preparation of nitrate of sodium with a half grain of camphor, continuing that six weeks after the attack has passed; I have found it to be an admirable sedative, and can heartily recommend it. My mother was a great sufferer from hay fever and asthma, and in 1885 I removed from her right nostril a large tumor, after which she had no trouble from hay fever or asthma until two years ago, when I found there was considerable hypertrophy existing in the left nostril, also in the right, together with a deflected septum, that by reason of my position in the family I had to refuse to operate on. About six weeks ago I removed an exostosis of considerable extent, and she writes me she had had no hay fever this season so far, and no asthma. I think there is great progress yet to be made and many things to be found out in the treatment of hay fever.

Dr. F. C. COBB, Boston. I would like to know whether in hay fever the writer includes vaso-motor or hyperæsthetic rhinitis? I have had some cases of that kind, and although in a good many of them I could not find any very marked nasal-obstruction, yet cauterization, not of a very wide area, but usually over the lower turbinated and points opposite to it on the septum, which seemed to be especially hyperæsthetic, appeared to give great relief, and a year later I heard from these cases that they had had very little, if any, hay fever. But those cases which were complicated with asthma still had asthma; there was very little relief from that. These were hospital cases operated upon year before last and they all had a great deal of trouble; some were complicated with polypi, which, of course, were removed. But all to whom I wrote reported very little nasal trouble, so I believe that cauterization, at least to a limited extent, is of considerable value.

Dr. J. H. BRYAN, Washington, D. C. I think there must be two conditions or else we would not have such diametrically opposite ideas, one of which is due to a morbid condition of the nose, which of course is relievable, but those cases in which in the interval of attacks there is no morbid condition I do not believe can be cured by local treatment, yet the symptoms can be greatly palliated. I think in this locality we have as much hay fever as anywhere in the country and I have seen quite a number of cases. Those which have been dependent upon exostosis or pressure of the turbinated bodies have been easily relieved and have not returned, but those which are entirely neurotic in character, where in the interval of the hay fever attacks, as far as observation goes, it is impossible to see any morbid condition invariably return, in this part of the country, about the 15th of August. I can not understand why there should be a discrepancy of opinion. Dr. Roe and Dr. Logan are positive the condition is not due to anything but intranasal disturbance, but I have two cases in which I think it is impossible to find anything existing in the nose in the interval of the attacks.

Dr. E. FLETCHER INGALS, Chicago. I did not intend to say anything upon this subject, but I am so heartily in accord with the last speaker that I wish to amplify and support what he has said. I have thought for a long time that where there is nothing discoverable in the nose during the interval, treatment of the nasal cavities is useless. Where there is something discoverable that gives the patient discomfort, treatment of the nasal cavities may be valuable. I have seen several cases where there was no hypertrophy or other form of obstruction, in which there was hyperæsthesia, and in these cauterization has been beneficial. As to the time of cauterization, my plan is to complete it at least two or three weeks before the attack is expected, so as to allow the mucous membrane to become healed before the onset of the disease. The cauterizations are rarely made oftener than once in five days, and cover an area of not more than a centimeter in diameter. The burn is superficial, never destroying the mucous membrane. Such cauterization has an effect similar to that of a blister on the skin, and after the treatment it is impossible to find cicatricial tissue. In some cases where there is much swelling, deeper linear cauterizations are necessary. I do not favor removal of the turbinated bodies in the way suggested by one of the speakers, believing that it is not best to destroy so much of the mucous membrane. If I wished to remove the turbinated bone I would run a trephine or burr through it, beneath the mucous membrane, thus removing enough of the bone so the soft tissue would fall to the side and be out of the way.

I have seen one case in which daily soothing treatment alone, carried out by the patient for a period of two years, prevented recurrence of the attacks. I have seen one case in which no topical or general treatment was employed, in which the patient, when the attack came on, by force of will never sneezed if he could possibly avoid it and persistently refrained from blowing or wiping the nose. As a result of this course he had only a slight attack the first year it was tried, and the next year practically none. I hope some of the other gentlemen will tell us what can be done by general treatment. It seems to me that half of the cases can be relieved, perhaps cured, by local treatment during the interim; but if the patient comes to us after the attack has been established local treatment is not important excepting to soothe the parts. A day or two ago a physician who has been troubled with hay fever told me that he has a rheumatic diathesis for which he has recently taken a few grains of salicylate of soda, which he feels confident is preventing him from having hay fever this season. It may be that the gouty condition causes hay fever in many cases, the rheumatic condition in others, and I have no doubt that digestive disorders have much to do with it. For my own part, I rely much upon a general tonic and sedative treatment similar to that recommended by the late Morell Mackenzie, consisting of the phos-

phate of brucia combined with camphor, hyoscamus, salol, and sometimes with valerianate of quinine. I have used this treatment for two or three years, I think with much advantage. I begin the treatment three or four weeks before the attack is expected, and have the patient continue it throughout the season.

Dr. JOHN N. MACKENZIE, Baltimore. I have been very much interested in the discussion and I am very much pleased that the word pollen has not occurred in the remarks made. The day is dawning when we will find a solution of this problem in the study of pathological law and not in an inquiry into the processes of plant reproduction. It is difficult to disassociate the pathology of hay fever from its treatment, because the latter depends upon what is conceived of the former. The pollen theory I regard as the greatest bar we have had to the march of therapeutics in this disease, and next to that I am afraid we are having another barrier set up in the too exclusive theory of the nasal nature of the malady. If we view it from the higher vantage ground of general pathology and laws of health we may catch a very much broader glimpse of the protean aspects of the problem and be in a much better position to relieve our patients than if we follow the beaten track of the pollen theorists. I certainly see cases in which there is no respiratory lesion whatever during the interval between the attacks. When I first began to investigate this matter I was allured by the new theories concerning the disease and for a long time was completely under their dominion, but further examination and broader conceptions of the disease have taught me the lesson that in a goodly proportion of the cases there is no appreciable local respiratory lesion whatever. Another point: It is not in the nose alone that these lesions are found; the area in which the nerve storm breaks will depend upon the seat of the local pathological process. For example, take a neurasthenic with a polypus in the rectum, the nervous disturbance produced by the polypus would be referred to the lower bowel, whereas in the case of a polypus in the nose the impressions would be referred to the upper respiratory tract. These lesions, when they do exist, as they undoubtedly do, may exist in the nose, pharynx, retro-pharynx, larynx, bronchial tubes, and trachea even. The point I wish to make is that the nose alone is not the only part of the respiratory tract that is responsible for the outbreaks of the disease falsely called hay fever. A great deal has been said in recent years about pressure irritation, but it seems to me that instead of producing hypertrophy it is more likely to produce atrophy. Take as an illustration cases to which the middle turbinated bone is enormously developed; as it gets larger and larger instead of producing hypertrophy of the septum it produces atrophy, and goes through to the other side.

Dr. Cobb has brought up the question of the identity of these different forms. They are all blood relations—coryza, vas-motor hay fever, rose cold, June cold—and if we should classify them as one disease it would simplify matters very much.

As to the plan of treatment, my rule has always been to examine the patient, going over him from head to foot, finding out any peculiarity, any disease, general or local, that might be the source of any systemic, local, or remote irritation. They are all different, like the stars, and in that way you get at a more rational plan of treatment. Having done that, I look carefully after any disease, either gross or microscopic, in the respiratory passages, not in the nose alone, but all through the tract, from the tip of the nose to the bronchial tubes. After having found the general condition I treat according to the circumstances of the case.

Dr. Ingals wishes to know about the general tonic treatment. I can not give any rule. I feed the nervous system; it is always broken down. We do not always find conspicuous nervous phenomena among hay-fever patients, but there is always a nervous organization—a screw loose somewhere in the nervous mechanism. I generally start out with a pill containing about one-sixteenth of a grain of phosphide of zinc, about 2 grains of quinine, one-fourth grain of extract of

nux vomica, to be taken before meals, and after meals 3 to 5 drops of Donovan's or Fowler's solution in water. Very frequently I have to substitute some other nerve tonic, but the main point is that the nervous system must be braced up. If there be disease of the respiratory organs, remove it if possible. If there be no apparent disease, and if upon experimental stimulation of different portions of the mucous membrane no sensitive areas are to be found, let it severely alone. But if, on the contrary, as is frequently the case, we can localize these areas I treat them by cauterization, and for this purpose the galvano-cautery transcends all other methods. We find these sensitive areas not only in the places where I have located them in the nasal passages, but also in other portions of the respiratory tract, in the posterior wall of the pharynx, in the arytenoid commissure, and the posterior wall of the trachea. Why is it that the removal of a nasal polypus, for example, will dissipate hay fever permanently? The explanation, it seems to me, is this: Take an illustrative case; the patient consults his physician, perhaps suffering from violent paroxysms of sneezing, obscure cough, and other symptoms referable to some reflex producing agency. The patient goes on unrelieved day after day. Asthma is finally added to his symptoms, and finally he blooms out into a regular hay-fever patient. If it is summer the physician tells him he has hay fever; if it is winter he is told he has asthma. At this stage of the disease a polypus is discovered and removed and the reflex symptoms are dissipated, and the patient gets well. What is the explanation of that? No attention has been paid to the central nervous apparatus; simple operative work in the nose has secured the result. In this class of cases the way in which the nervous system is influenced is through the constant irritation by the foreign body in the nose; the irritation of the nerve centers, the weariness they experience at being forever called upon to discharge their functions. With the removal of the polypus the irritation is taken away and physiological rest secured for the centers, and in that way the patient gets well. If the polypus remains unrecognized the condition goes on for years, other organs are included in the arc of reflex disturbance, changes occur in different organs which are impossible of eradication, and local treatment alone will lead to temporary relief, but will not effect a permanent cure. In regard to surgery; it is called for when surgery is necessary, and it is only necessary when there is something pathological to be removed from the respiratory apparatus.

Dr. JOHN N. MACKENZIE, Baltimore. I omitted to make an important point, and that is that hay fever does not exist only at one time of the year. I believe it is like epilepsy, with you day and night, summer and winter. One of the worst cases of hay fever I ever saw was a lady in Baltimore, whom I treated for four successive Januarys. She never had it in any other month; it was a marked case of hay fever, with asthma. My plan is not to commence with a tonic at the period of attack, but I commence from six to eight weeks, sometimes three months, before the expected attack, and I feed the nervous system for all it is worth during that time; and I not only do that but I treat the patient through the year at certain intervals, depending upon the patient, the character of the case, etc. I treat them during the entire year as if they were just on the verge of a paroxysm, and one of the chief difficulties I have is to follow my patients. They will get apparently well, and will think "this is all humbug; I don't feel nervous; I am not going to have a paroxysm for six or eight months, and I will let the thing drop."

Dr. D. BRYSON DELAVAN, New York City. The Doctor has referred to one of the most important points in view in bringing forward this discussion. It can not be too vigorously emphasized. We so often see patients and physicians putting off treatment of this disease until the attack begins. The golden opportunity for treatment, according to my experience, is the interval between the attacks, especially in those cases where there is present any nasal or constitutional trouble. I have seen cases in which during the intervals between the

attacks the nasal condition seemed to be normal, and although I have used my best endeavor to find an abnormality, I have not succeeded. However, we commonly have hypertrophic conditions, catarrh, exostosis, nasal polypus, and various other deformities present, and these conditions persist, to a greater or less degree, throughout the year. We can all agree to the following propositions: First, that the general condition of the patient should be kept up to the best possible limit; second, that the best opportunity for relieving the patient will be found between the attacks, when abnormal conditions of the nose should be treated, whether by surgical or therapeutical measures to be determined by the nature of a given case; and, third, that during the attack the treatment applied should have for its prime object the alleviation of the existing symptoms.

In regard to treatment during the attack, I think it would not be unwise for this body to place itself on record as distinctly opposed to the indiscriminate and careless use of cocaine. What one of the gentlemen said with regard to this matter in his locality might have been said, I think, by everyone present. We all find it commonly used and commonly abused. It is a source of a great deal of injury, and I wish we might go on record as opposing the evil.

Finally, the fact has not been touched upon, although we all recognize it, that when our therapeutical and surgical means are exhausted certain relief may be obtained by placing the patient in a proper climate, where he may enjoy immunity from his attacks. I believe that in this class of cases, where the patient can be sent away during the time he is having his attack, and where he can be treated between the periods of expected attack, in time the attacks may be entirely done away with in a fair proportion of instances.

Dr. JOHN N. MACKENZIE, Baltimore. I wish to indorse what Dr. Delavan has said in regard to the use of cocaine. I have long since given it up in the treatment of this disease except as a purely palliative measure. At a meeting of the Laryngological Association some years ago in Detroit I called attention to the fact, shortly after the drug was brought over to this country, that the time came sooner or later when cocaine dilated the blood vessels in the mucous membrane of the throat and nasal passages, and I think that point is now perfectly well established, and Dr. Delavan's denunciation of its indiscriminate use is correct. But there is another point not generally known, namely, the evil effect menthol sometimes produces. I know of two cases in the practice of a fellow practitioner in which menthol has given rise to brain symptoms similar to those cocaine produces. The patients were both singers and had learned that a little menthol squirted into the nose with an eye dropper just before they were going to sing would make their voices more resonant, so it had become their practice every time they were to sing to drop in a little of this seemingly harmless thing, and finally the friends of one of them noticed that she was having hallucinations and that her mind was becoming otherwise affected. This was spoken of to a physician, and when she ceased taking the menthol all her bad symptoms disappeared. The other case was affected in the same way and on discontinuing the use of menthol became well again.

---

## THE ULTIMATE PROGNOSIS IN NEGLECTED ADENOID HYPERTROPHY.

By D. BRYSON DELAVAN, M. D., of New York.

The effects of adenoid hypertrophy upon the general well being of the patient have been so thoroughly exploited during the past ten years that they are, or should be, abundantly recognized and understood by all practitioners of medicine. To discuss the injury to the hearing, the deformities of the jaw, the nasal cavities, the face and the thorax, the defects of speech, or the impairment of nutrition due

to adenoid hypertrophy would be to present facts which are already sufficiently familiar. It will be the object of this paper to avoid the above considerations, and to invite attention to a series of important conditions which, in the opinion of the writer, are more or less the result of neglected adenoid enlargement, or of incomplete removal of it during attempted operation, but which have not always been recognized as bearing direct relation with that disease.

The existence of the conditions which we are about to consider must depend upon the oft-repeated question: Does adenoid hypertrophy, if left to itself, tend to disappear, leaving the pharyngeal vault in a normal, healthy state? By a universal consensus of opinion, founded upon common observation, the reply is negative. Adenoid hypertrophy, if left to itself, will seldom result in spontaneous cure, no matter what modifications it may undergo, but will usually leave behind it local pathological conditions which may continue for life, to the permanent inconvenience and detriment of the patient. This is proved by the frequency with which the history of preëxisting adenoid hypertrophy is traceable in these cases. The conditions above alluded to are the direct outcome of the structural changes which occur in the third tonsil, as elsewhere, as the result of long-continued inflammation. They may be classified broadly under two heads: (1) A condition of permanent enlargement or thickening. (2) A condition of genuine atrophy. (3) Finally, as a probable subdivision of class 1, we may have the condition known as "Thornwaldt's disease."

*Class 1.*—The existence of this class of cases is proved without difficulty, since they are commonly met with in practice and easily recognized. Belonging to it are several varieties, which may be summarized briefly as follows:

(1) Cases in which the hypertrophy of childhood remains, with slight diminution in size, until past middle life. Examples of this form may be found in persons well along in life. Indeed, Dr. J. Solis-Cohen has reported one case occurring in a woman of over seventy years of age. Cases are often met with in singers and speakers whose voices show distinct evidence of the pharyngeal disease, and who often fail to obtain satisfactory relief until the offending tissue has been thoroughly removed. The hypertrophy is seldom as pronounced as in childhood, but a sufficient amount remains to constitute a well-marked projection from the pharyngeal vault and a consequent interference with the normal amount of space required for that region.

(2) Cases in which, with considerable diminution in the size of the original growth, a moderate enlargement remains, which in some cases is subject to acute attacks of swelling, during which may be developed, temporarily, a well-marked pharyngeal tumor. In this condition of the vault there often appears, upon examination, to be nothing more than a simple thickening of the mucous membrane without especial significance. In reality, it is the remnant of an early hypertrophy, and constitutes in itself a morbid state, attended with annoying symptoms. This particular class of cases presents several interesting features. Often the usual appearance of the vault differs little from the normal, excepting that the color may be darker than usual and the surface of the mucous membrane somewhat less smooth. The application of the finger tip, however, or of the end of a probe, will demonstrate the presence of a distinct thickening which may be so slight and so generally distributed as to be overlooked, although overlying the whole vault.

(3) The so-called "Thornwaldt's disease" is described as being a chronic inflammation of the "pharyngeal bursa," accompanied with some enlargement, and a discharge from one or more of the crypts or folds at the pharyngeal vault. It appears to be nothing more than a chronic condition resulting from long-standing hypertrophy. Certainly it is best treated by the same means which are successful in cases of ordinary hypertrophy, namely, by the removal of the offending tissue.

In all of the above varieties of pharyngeal disease there is commonly present a remarkably persistent catarrhal inflammation, in some cases much more severe than in others, and attended with greater disturbance to adjacent parts, but in nearly all sufficiently well marked to be the cause of distinct annoyance. It is in such cases also that progressive loss of hearing is apt to occur. While the habit of mouth-breathing may have been long ago successfully overcome, the effect upon the voice of the interference with the normal contour of the vault of the pharynx, caused by the thickened tissue projecting into it, and of the presence of the unnatural secretions which more or less occlude it, is particularly unfortunate, materially impairing its richness and tone quality even when it does not interfere with pronunciation.

The second class of cases is one in which the conditions and symptoms are even worse than those of class 1. In them the soft parts of the pharyngeal vault have undergone a distinct atrophy. Their anatomical structures have either been completely destroyed or else so modified that they are no longer able to perform their normal functions and the physiological activity of the parts has thus been destroyed. Local symptoms of a distressing nature also are set up and a most unfortunate state of affairs is the final result. It is not claimed, of course, that all cases of atrophic catarrh of the vault are consecutive to adenoid hypertrophy. On the contrary, it is not uncommon to find this disease in patients who, to all appearance, and so far as their histories go, have been remarkably free from lymphoid enlargements of all kinds. Nevertheless, severe degrees of dry pharyngeal catarrh are not seldom found in patients in whom unmistakable evidences of pre-existing adenoids are present.

If the conditions described under class 1 are objectionable, those last mentioned are far more so, both with regard to the discomfort and annoyance which go with them and to the extreme difficulty which attends their cure. All, however, are objectionable in a high degree and eminently calculated to add to the burdens of life, while detracting from the comfort and general usefulness of the patient.

To sum up, it appears: (1) That there are several pathological conditions of the upper pharynx found in adult life. (2) That these conditions are common. (3) That where they are present the history of preëxisting adenoid hypertrophy can often be distinctly traced. (4) That the conditions which are present in these cases of adult disease are such as would have resulted naturally from the effects of long-continued inflammatory action upon the parts concerned. (5) The above premises being true, it is impossible to avoid the inference that prompt and efficient treatment of the original adenoid enlargement would have removed the chief cause of the subsequent disease, and thus have prevented much injury and suffering.

The great frequency therefore with which disease of the vault of the pharynx, due to neglected adenoid hypertrophy, is found, the serious character of the conditions resulting from it, and the great difficulty often experienced in overcoming them, all bear testimony to the fact that, on the whole, adenoid hypertrophy does not tend to spontaneous cure; that when present, in any marked degree, it demands thorough treatment, and finally that if left to itself in the hope of spontaneous cure the ultimate prognosis is bad.

The practical application of the above conclusions is obvious. Adenoid hypertrophy is a disease which is always likely to be injurious. Its effects are not confined to childhood, but may follow the patient as long as he lives; and with regard to its treatment, the greatest amount of evil is to be avoided and a maximum of good obtained by its early, thorough, and complete removal.

## DISCUSSION.

Dr. PRICE-BROWN, Toronto. I would like to ask whether the Doctor finds a greater proportion of cases of hypertrophy in the adenoids in males or females; also whether there is any direct hereditary tendency to the disease? As a rule, I have found a larger number occurring in males than females. In children who have been brought to me for treatment of adenoids, I have frequently found that where the father had the disease, the sons had it also. I would like to know whether there is any connection between the two.

Dr. D. BRYSON DELAVAN, New York City. In answer to Dr. Brown, I have not observed any distinct preponderance in either sex. There is no question as to the possibility of heredity. Either the child inherits the adenitis itself or he inherits tertiary syphilis, or tuberculosis, which may develop adenitis, which amounts to the same thing. As to nationality, that nation will have the most adenitis which is the most exposed to damp, changeable, chilly weather, and perhaps to tuberculosis and the various diatheses that accompany bad climatic surroundings, although in the healthiest American types adenoid enlargement may be found. The subject of the paper is the tendency of neglected adenitis to continue as a source of irritation and disease during adult life, and it was for that point alone the paper was presented, because I think sometimes this tendency to degeneration and permanent pathological results is not sufficiently realized.

---

THE EFFECTS ON THE VOCAL CORDS OF IMPROPER METHOD IN SINGING.

By H. HOLBROOK CURTIS, M. D., of New York.

It would be strange indeed if a laryngologist who was daily in the habit of examining very many throats of singers did not have his attention particularly attracted to the difference in the appearance of the glottis as the direct result of different methods of voice production.

Several years ago, as early as 1884, I observed that many pupils of a certain professor of singing presented marked peculiarities in regard to the position of the free borders of the vocal bands. The slightly elliptical shape of the chink of the glottis, which this class of pupils presented in emitting the usual sounds to allow the proper view of the larynx, led me to inquire as to the particular method of teaching which would produce in so many throats a typical appearance. I soon found out that these pupils were in the habit of taking daily exercises almost entirely on a single vowel, and that single vowel being the letter "o." The vocal cords appeared striated, with frequently a congested area at their anterior attachment. Frequently a nodule, more or less defined, would be observed about the center of the free edges on either cord. This is a picture which every laryngologist will recognize. Another type of which the study is most interesting is that of a class of pupils undergoing instruction at a conservatory where that pernicious French method, the so-called stroke of the glottis (*coup de glotte*), is daily practiced. In this type the writer has observed the middle-third of the cords to be slightly bulged, the cords presenting a convexity in contradistinction to the concavity exhibited in the last group.

These pupils had been singing chiefly on the vowel "a," pronounced as "ah" in English, and with the emission of each note the middle portion of the cords would clash, and by constant attrition become hardened and callous. The cords in this particular type do not usually show congestion; their appearance is usually of a

good pearl color, and healthy looking in every way. The complaint which they make upon consultation is a difficulty in singing the so-called mezzo voce and a lack of richness of tone and timbre, with extreme weakness of two or three notes in the upper medium register. It was these two opposite appearances of vocal cords, which are every day observed in singers' throats, that led to an investigation of methods employed by the various schools of singing, and has opened up a field which I think has been entirely neglected, though of the greatest importance to every laryngologist who has to do with singers.

Two names are intimately linked with the traditions of method in singing—those of the elder Lamperti (that illustrious exponent of the best Italian school), and Mandl, who, by his ingenious arguments, though founded on a false physiological basis, succeeded in completely overturning the art of voice production which previously had been taught throughout Europe. He substituted in place of the so-called Italian school a method of abdominal respiration which was at once adopted in the Paris conservatory, and has obtained to within the last three years an almost universal recognition in the best schools of the Continent.

It is the writer's purpose, without going too deeply into the history of singing, to discuss the various methods of respiration and initial tone production, and to show by a series of experiments made upon individuals the effects of certain methods of voice building, hoping to arrive at some definite conclusion as regards the proper exercise and position of the larynx, and consequently proper tension of the vocal cords during tone emission. For the brief historical sketch which I shall give I am indebted almost entirely to the able article of Dr. Joal, of Mont-Dore, which appeared in the *Revue de Laryngologie d'Otologie et de Rhinologie*, Nos. 8, 9, and 10, 1892, Paris. The position which Dr. Joal occupies at Mont-Dore (the favorite resort of almost all the European artists) has enabled him to consult freely for a number of years the most distinguished vocal talent in Europe, and his views upon voice production should be carefully read by every instructor who wishes to profit by the exceptional opportunities which that author has enjoyed. One can not read his able discourse upon the singing voice without feeling that his every utterance is *ex cathedra*. In 1842 Beau and Maissait divided the respiration of singers into three characteristic types—the superior costal, inferior costal, and abdominal. The superior costal may be illustrated as the breathing of a woman tightly laced, the respiratory expansion taking place chiefly in the cone of the thoracic cavity, the upper ribs, collar bone, and sternum rising and falling during the respiratory act. In the inferior costal type the inferior ribs (commencing with the seventh downward) are rotated and elevated, the sternum moving only in its inferior portion, the abdominal wall being contracted during the inspiratory act. In the true abdominal type, the thorax is supposed to remain completely fixed, the diaphragm, taking the ribs as a fixed point, lowering the abdominal viscera, thus distending the wall of the abdomen in inspiration. It is this latter type of breathing which has been taught for the last thirty years in France.

Mengozzi, together with the masters of one of the conservatories, determined upon the following rules illustrative of the breathing of singers:

The respiratory act in singing differs somewhat from that used in speaking. In speaking the abdomen is distended in inspiration and recedes in expiration, while in singing the abdomen must be drawn in during inspiration, returning slowly to its natural state as the chest contracts in expiration; thus retaining as a negative force the air which has been introduced into the lungs.

In a revision of this method, published in 1866 by Baptiste, these laws are repeated with the addition of a note by Dr. Mandl (the apostle of abdominal respiration) who advocates the advancing of the abdomen in inspiration. Mandl carried his point, and his ideas became generally adopted by the conservatory. M. Bonheur and Dr. Cheval, of Brussels, advocated the superior costal type of breath-

ing in contradistinction to the method of Mandl. Mandl in his work states that the larynx becomes very much depressed and the glottis enlarged in the costal method of respiration. Joal answers him in these words:

We do not find this depression of the larynx referred to in any of our classical treatises on physiology, anatomy, nor in any of the numerous works which have appeared since 1855 on laryngology; consequently we suppose that writers do not share the ideas of Mandl on the subject. Besides we have examined a number of persons whom we engaged to breathe alternately from the abdomen and from the shoulders. We ourselves, in singing, have often observed the movement of our larynx and we have never observed that the clavicular inspiration caused the thyroid to fall.

Nicaise explains this fact by demonstrating experimentally that during strong inspiration the trachea contracts and becomes shorter, which draws down the larynx.\*

It is very difficult for a professional man to take cases of distinguished singers in his own private practice and hold them up by name as models of perfection of certain types. Joal made the assertion, in an article published in 1890, that great artists, especially women, used the superior costal method. The distinguished critic of *Le Temps* challenged Dr. Joal at once to mention some of these artists. The Doctor responded:

I would be happy to gratify Mr. Weber's desire, but it is very difficult for a physician to go into personalities and to say that a certain singer is using a vocal method considered disastrous and execrable by masters of criticism.

Melchisedec, however, offered himself as an example of the superior costal respiration, saying that it had enabled him to sing constantly for twenty-five years. Both his strength of tone and his tremendous endurance, with an almost perfect glottis, attest that the method has not been injurious to him.

The abdominal method of breathing has many powerful advocates. M. Obin and M. Faure, for example, speak most highly of it; Shakespeare, of London, Behnke, and Lennox-Brown are also its advocates. The instructors of both methods are very apt to quote great artists as the exponents of their particular school. Joal cites the case of Rubini, the celebrated tenor, whom Massini and his pupils declare originated abdominal respiration. Bonheur, on the contrary, states that he expanded his upper chest, Walshe even going so far as to say that he fractured his collar bone in making a violent effort to reach "B flat" in "The Talisman of Pacini." Lablache and Laget acknowledged that in spite of long and attentive observation they had not been able to distinguish in the theater how this illustrious tenor breathed. Joal goes on to state that the famous Lamperti is alternately represented as a partisan or opponent of the abdominal type of breathing; but I think that, having treated many of the elder Lamperti's pupils and interrogated them very particularly upon this question, I may unhesitatingly affirm that the elder Lamperti was a strong advocate of the lower costal respiration, always arguing that the abdominal wall should remain quiet or be slightly drawn in during inspiration. The evidence of Campanini, Jean de Reszke and Clara Heyen is in support of the above. Joal says if we except the works of Laget and Bonheur, we find nowhere the praise of clavicular breathing in men. The ancient method of the Paris Conservatory and the works of Maunstein, Caruth, and Manuel Garcia all advise thoracic respiration by the elevation of the ribs and drawing in of the abdomen.

If we take up any work on the voice and study the photographic appearances of the cords during the emission of certain notes, we remark that the cords are not vibrating longitudinally, but that their free borders approximate, touch, or overlap, and that the posterior opening of the chink is longer or shorter, and different

---

in appearance for each note. I wish to put on record here my opinion of the absolute impossibility of photographing the vocal cords during the proper emission of tone, from the very fact that the laryngoscopic mirror placed in the pharynx interferes with the right focus of the respiratory attack, and it is only possible to observe the vocal cords in the photograph when the so-called stroke of the glottis is used in the emission of a note. The photographs of singers' cords and the deductions which have been drawn from their appearance during the emission of different notes only demonstrate, in every case that I have ever seen, that the larynx is elevated by the pulling up of the thyroid, the cords relaxed, and the free borders more or less approximated.

If we ask a singer who is in the habit of using the so-called "high-chest method" of costal respiration to take a note (the attack entirely taken from the cords and focused in the masque, bringing into play the harmonics lent by the sound waves passing behind the uvula and soft palate), introducing the smallest possible size of mirror, so that the color given to the note by nature's resonance pipes, the antra and nasal cavities, will be as little as possible interfered with, we are surprised to find that on the emission of every note of the soprano medium register the cords appear equidistant from each other throughout the entire extent that it is possible to see them.

The part which the intrinsic muscles of the larynx play in the tension of the vocal cords becomes an interesting study. It is very easy for us to see by the depression of the thyroid how the cords must be elongated, but it is extremely difficult for us to comprehend the minute differences of tension caused by the movements of the thyro-arytenoid and crico-arytenoid muscles. I have frequently been surprised, upon examination of the vocal cords with the head held down, the chin resting upon the chest, to find the cords present a beautiful pearly appearance, entirely homogeneous, but upon attempting to show the patient his own cords by an adjustment of double mirrors, the head being slightly thrown back, upon the same note the cords suddenly have become dusky, semi-congested, and striated. How much of this is due to the slight elevation of the thyroid cartilage, and how much to the intrinsic muscles of the larynx or to the relationship between the chink of the glottis and the trachea, it is difficult to determine. To a careful study of these differences of tension am I indebted for the discovery of a fact which I here write about for the first time, the appreciation of which fact, however, has entirely changed my treatment of the singing larynx, and has caused me to institute a system of tone exercises by which certain intrinsic muscles of the larynx are so strengthened that any medical application through the medium of sprays, probangs, and, I may say, instrumentation, has oftentimes been entirely done away with.

If we take a good-sized laryngoscopic mirror, No. 4, for example, and ask a patient to sing "E" or "Ah," the cords come into view for two reasons: First, the epiglottis becomes more perpendicular, allowing a better view of the bands, and secondly, the cords themselves are on a more elevated plane, owing to a slight elevation of the thyroid cartilage and consequent relaxation of the intrinsic tensors of the cords. In this position we remark that the free borders of the cords come together in the anterior and central portions, and we are able to study the initial tone attack, the membrane separating as the tone bursts through the closed chink. This picture may be said to be an imitation on a small scale of the so-called stroke of the glottis. In this method of producing a tone, the initial attack being upon the cords themselves, the central portions of the cords necessarily touch. The peculiar muscular equilibrium which is employed in this mode of attack invites a reflex elevation of the soft palate, cutting off the oral from the nasal cavities. As we look at this picture our minds revert to the singing teacher who commands her pupils to keep their palates up, sing in the back of their heads and strike the glottis.

Could ever villainy be more compounded? Let us take the same patient and require him to sing the same note, but in an entirely different way. We will first ask him to expand his upper chest, not necessarily by respiration, but by elevation of the superior ribs by a muscular effort, at the same time slightly drawing in the abdominal wall. We now introduce the smallest mirror and ask our patient to sing "A," pronounced as in "law" or "maw." With this position of the larynx and muscular poise, we observe two things: First, the epiglottis does not assume its most vertical aspect, not inclining as near the perpendicular, and the soft palate and uvula do not spring upward and backward to make the partition between the mouth and the naso-pharynx. Different in every respect is the tone produced by the cords, which may be assumed to vibrate longitudinally, but never touching each other in the middle portion, even in making the initial attack. The cords appear narrower, tenser, lower anteriorly, equidistant from each other, more homogeneous and whiter in color.

These two pictures should be well considered, as they become the basis of criticism in distinguishing the correct and eliminating incorrect methods, on the one hand, in singer's voices, and of the greatest assistance to the laryngologist in correcting pathological conditions, the result of bad training. The proper appreciation of these opposite conditions and their effect on the quality of tone immediately calls our attention to the subject of respiration. Within the past three years the entire theory of musical education has changed in France. The explanation of this change being that there is at present a better appreciation of the influences bearing upon the production of tone, and a better understanding of the physiology of the larynx by reason of the advances made in laryngoscopy. Modern teaching tends to cultivate tone harmonies and *sympatica* in the voice at the expense of brilliancy of execution. The same judgment should be exercised in the training of an individual who proposes to make singing his or her art as should be employed in advising the painter that his special forte lies in landscapes, rich in color, to which he may give expression to his imaginative genius, rather than to the sterner fac simile of portraiture. How many singers we hear whose technique and brilliant staccato in the Bell Song of *Lakme* calls forth our admiration and amazement, but who are absolutely unable to put any *sympatica* whatsoever into the simplest ballad. We should study color harmonies in music in the same way that they must be studied in painting. There is no rule for the palpitating sunlight effects and prismatic play of colors in the school of Claude Monet; it is certainly a subtle feeling which is given by an ingenious mingling of pure spectrum colors.

In the human voice, that added coloring of tone which appeals to the heart as well as to the ear of the listener must be brought about by the employment of those harmonies which are added to the original tone by intervibrations within the accessory cavities of the nasal passages. To sing *dans le masque*, as the French say, is to give this added richness to the initial tone; but to sing in this manner requires the soft palate and uvula to be lowered in the production of tone. Likewise, to make the purest initial tone from the cords we must get the utmost possible tension, which may only be arrived at when the thyroid is depressed; for, in proportion as the thyroid is elevated, the cords tend to assume the base of a right angle triangle instead of its hypotenuse. Several elements beside this enter into the question of greatest possible tension, one of the most important of which is, that the trachea be drawn down to assume the position that it takes when the apices of the lungs are filled to their greatest extent with air. One of the greatest singers that the world has ever known told me that the reason that he adopted a fixed high chest was that he had found, after the removal of a papilloma from one of his cords, that the only way in which he could be at all sure of his voice while singing was the maintenance of the so-called "high-chest respiration." This is

easily explained by the fact that in this position the upper ribs remaining fixed, the apices of the lungs always remain in contact with the thoracic wall, expanded to their fullest extent, the cords being kept in their state of greatest possible tension. In this position the breathing becomes entirely inferior, costal, and diaphragmatic. The position of the thorax, as indicated above, permits the lungs to expand to their fullest extent, thus adding a secondary resonance to the voice from below—a sort of complementary timbre—the fixed upper thorax allowing of the least possible change of color during tone production.

It is this combination of facial and thoracic tone fortification which gives the enormous carrying power to tones produced by this method. For a number of years, before I made a special study and estimated the great significance of these factors in singing, I have deluged the throats of singers with sedative and astringent sprays when their cords appeared congested and swollen, often presenting nodules in their center which I had never previously recognized as being due entirely to singing with an improperly poised larynx.

I may cite several cases to show you the difference, from a medical standpoint, in the treatment of the singer's throat, where I now substitute respiratory and tone exercise for the amelioration of conditions, that I have always been taught were only to be cured by rest and the diligent use of drugs. The cases I cite are typical of a class of singers that I have treated with equally good results since I have made a particular study of the peculiar value of the proper tone production in the human voice.
